- All invocations have a configurable timeout after which they fail, returning a OperationCanceledException to the caller.
  - There's a default timeout for the calls (CircuitOptions.JSInteropDefaultCallTimeout) of one minute. To configure this limit, see Call JavaScript functions from .NET methods in ASP.NET Core Blazor.
  - A cancellation token can be provided to control the cancellation on a per-call basis. Rely on the default call timeout where possible and time-bound any call to the client if a cancellation token is provided.
- The result of a JavaScript call can't be trusted. The Blazor app client running in the browser searches for the JavaScript function to invoke. The function is invoked, and either the result or an error is produced. A malicious client can attempt to:
  - Cause an issue in the app by returning an error from the JavaScript function.
  - Induce an unintended behavior on the server by returning an unexpected result from the JavaScript function.

Take the following precautions to protect against the preceding scenarios:

- Wrap JS interop calls within try-catch statements to account for errors that might occur during the invocations. For more information, see Handle errors in ASP.NET Core Blazor apps.
- Validate data returned from JS interop invocations, including error messages, before taking any action.

.NET methods invoked from the browser

Don't trust calls from JavaScript to .NET methods. When a .NET method is exposed to JavaScript, consider how the .NET method is invoked:

- Treat any .NET method exposed to JavaScript as you would a public endpoint to the app.
  - Validate input.
    - Ensure that values are within expected ranges.
    - Ensure that the user has permission to perform the action requested.
  - Don't allocate an excessive quantity of resources as part of the .NET method invocation. For example, perform checks and place limits on CPU and memory use.
  - Take into account that static and instance methods can be exposed to JavaScript clients. Avoid sharing state across sessions unless the design calls for sharing state with appropriate constraints.
    - For instance methods exposed through DotNetObjectReference objects that are originally created through dependency injection (DI), the objects should be registered as scoped objects. This applies to any DI service that the app uses.
    - For static methods, avoid establishing state that can't be scoped to the client unless the app is explicitly sharing state by-design across all users on a server instance.
  - Avoid passing user-supplied data in parameters to JavaScript calls. If passing data in parameters is absolutely required, ensure that the JavaScript code handles passing the data without introducing Cross-site scripting (XSS) vulnerabilities. For example, don't write user-supplied data to the DOM by setting the `innerHTML` property of an element. Consider using Content Security Policy (CSP) to disable `eval` and other unsafe JavaScript primitives. For more information, see Enforce a Content Security Policy for ASP.NET Core Blazor.
- Avoid implementing custom dispatching of .NET invocations on top of the framework's dispatching implementation. Exposing .NET methods to the browser is an advanced scenario, not recommended for general Blazor development.

Events

Events provide an entry point to an app. The same rules for safeguarding endpoints in web apps apply to event handling in Blazor apps. A malicious client can send any data it wishes to send as the payload for an event.

For example:

- A change event for a `<select>` could send a value that isn't within the options that the app presented to the client.
- An `<input>` could send any text data to the server, bypassing client-side validation.

The app must validate the data for any event that the app handles. The Blazor framework forms components perform basic validations. If the app uses custom forms components, custom code must be written to validate event data as appropriate.

Events are asynchronous, so multiple events can be dispatched to the server before the app has time to react by producing a new render. This has some security implications to consider. Limiting client actions in the app must be performed inside event handlers and not depend on the current rendered view state.

Consider a counter component that should allow a user to increment a counter a maximum of three times. The button to increment the counter is conditionally based on the value of `count`:

razor

```razor
<p>Count: @count</p>

@if (count < 3)
{
    <button @onclick="IncrementCount" value="Increment count" />
}

@code
{
    private int count = 0;

    private void IncrementCount()
    {
        count++;
    }
}
```

A client can dispatch one or more increment events before the framework produces a new render of this component. The result is that the `count` can be incremented *over three times* by the user because the button isn't removed by the UI quickly enough. The correct way to achieve the limit of three `count` increments is shown in the following example:

razor

```razor
<p>Count: @count</p>

@if (count < 3)
```

```
{
    <button @onclick="IncrementCount" value="Increment count" />
}

@code
{
    private int count = 0;

    private void IncrementCount()
    {
        if (count < 3)
        {
            count++;
        }
    }
}
```

By adding the `if (count < 3) { ... }` check inside the handler, the decision to increment `count` is based on the current app state. The decision isn't based on the state of the UI as it was in the previous example, which might be temporarily stale.

Protect against multiple dispatches

If an event callback invokes a long running operation asynchronously, such as fetching data from an external service or database, consider using a safeguard. The safeguard can prevent the user from enqueueing multiple operations while the operation is in progress with visual feedback. The following component code sets `isLoading` to `true` while `DataService.GetDataAsync` obtains data from the server. While `isLoading` is `true`, the button is disabled in the UI:

razor

```
<button disabled="@isLoading" @onclick="UpdateData">Update</button>

@code {
    private bool isLoading;
    private Data[] data = Array.Empty<Data>();

    private async Task UpdateData()
    {
        if (!isLoading)
        {
            isLoading = true;
            data = await DataService.GetDataAsync(DateTime.Now);
            isLoading = false;
        }
    }
}
```

The safeguard pattern demonstrated in the preceding example works if the background operation is executed asynchronously with the `async`-`await` pattern.

Cancel early and avoid use-after-dispose

In addition to using a safeguard as described in the Protect against multiple dispatches section, consider using a CancellationToken to cancel long-running operations when the component is disposed. This approach has the added benefit of avoiding *use-after-dispose* in components:

razor

```
@implements IDisposable

...

@code {
    private readonly CancellationTokenSource TokenSource =
        new CancellationTokenSource();

    private async Task UpdateData()
    {
        ...

        data = await DataService.GetDataAsync(DateTime.Now,
TokenSource.Token);

        if (TokenSource.Token.IsCancellationRequested)
        {
           return;
        }

        ...
    }

    public void Dispose()
    {
        TokenSource.Cancel();
    }
}
```

Avoid events that produce large amounts of data

Some DOM events, such as `oninput` or `onscroll`, can produce a large amount of data. Avoid using these events in server-side Blazor server.

Additional security guidance

The guidance for securing ASP.NET Core apps apply to server-side Blazor apps and are covered in the following sections of this article:

- Logging and sensitive data
- Protect information in transit with HTTPS
- Cross-site scripting (XSS)
- Cross-origin protection
- Click-jacking
- Open redirects

Logging and sensitive data

JS interop interactions between the client and server are recorded in the server's logs with ILogger instances. Blazor avoids logging sensitive information, such as actual events or JS interop inputs and outputs.

When an error occurs on the server, the framework notifies the client and tears down the session. The client receives a generic error message that can be seen in the browser's developer tools.

The client-side error doesn't include the call stack and doesn't provide detail on the cause of the error, but server logs do contain such information. For development purposes, sensitive error information can be made available to the client by enabling detailed errors.

> ⚠ **Warning**
>
> Exposing error information to clients on the Internet is a security risk that should always be avoided.

Protect information in transit with HTTPS

Blazor uses SignalR for communication between the client and the server. Blazor normally uses the transport that SignalR negotiates, which is typically WebSockets.

Blazor doesn't ensure the integrity and confidentiality of the data sent between the server and the client. Always use HTTPS.

Cross-site scripting (XSS)

Cross-site scripting (XSS) allows an unauthorized party to execute arbitrary logic in the context of the browser. A compromised app could potentially run arbitrary code on the client. The vulnerability could be used to potentially perform a number of malicious actions against the server:

- Dispatch fake/invalid events to the server.
- Dispatch fail/invalid render completions.
- Avoid dispatching render completions.
- Dispatch interop calls from JavaScript to .NET.
- Modify the response of interop calls from .NET to JavaScript.
- Avoid dispatching .NET to JS interop results.

The Blazor framework takes steps to protect against some of the preceding threats:

- Stops producing new UI updates if the client isn't acknowledging render batches. Configured with CircuitOptions.MaxBufferedUnacknowledgedRenderBatches.
- Times out any .NET to JavaScript call after one minute without receiving a response from the client. Configured with CircuitOptions.JSInteropDefaultCallTimeout.
- Performs basic validation on all input coming from the browser during JS interop:
  - .NET references are valid and of the type expected by the .NET method.
  - The data isn't malformed.
  - The correct number of arguments for the method are present in the payload.
  - The arguments or result can be deserialized correctly before invoking the method.
- Performs basic validation in all input coming from the browser from dispatched events:
  - The event has a valid type.
  - The data for the event can be deserialized.
  - There's an event handler associated with the event.

In addition to the safeguards that the framework implements, the app must be coded by the developer to safeguard against threats and take appropriate actions:

- Always validate data when handling events.
- Take appropriate action upon receiving invalid data:
  - Ignore the data and return. This allows the app to continue processing requests.
  - If the app determines that the input is illegitimate and couldn't be produced by legitimate client, throw an exception. Throwing an exception tears down the circuit and ends the session.
- Don't trust the error message provided by render batch completions included in the logs. The error is ***provided by the client*** and can't generally be trusted, as the client might be compromised.

- Don't trust the input on JS interop calls in either direction between JavaScript and .NET methods.
- The app is responsible for validating that the content of arguments and results are valid, even if the arguments or results are correctly deserialized.

For a XSS vulnerability to exist, the app must incorporate user input in the rendered page. Blazor executes a compile-time step where the markup in a `.razor` file is transformed into procedural C# logic. At runtime, the C# logic builds a *render tree* describing the elements, text, and child components. This is applied to the browser's DOM via a sequence of JavaScript instructions (or is serialized to HTML in the case of prerendering):

- User input rendered via normal Razor syntax (for example, `@someStringValue`) doesn't expose a XSS vulnerability because the Razor syntax is added to the DOM via commands that can only write text. Even if the value includes HTML markup, the value is displayed as static text. When prerendering, the output is HTML-encoded, which also displays the content as static text.
- Script tags aren't allowed and shouldn't be included in the app's component render tree. If a script tag is included in a component's markup, a compile-time error is generated.
- Component authors can author components in C# without using Razor. The component author is responsible for using the correct APIs when emitting output. For example, use `builder.AddContent(0, someUserSuppliedString)` and *not* `builder.AddMarkupContent(0, someUserSuppliedString)`, as the latter could create a XSS vulnerability.

Consider further mitigating XSS vulnerabilities. For example, implement a restrictive Content Security Policy (CSP). For more information, see Enforce a Content Security Policy for ASP.NET Core Blazor.

For more information, see Prevent Cross-Site Scripting (XSS) in ASP.NET Core.

Cross-origin protection

Cross-origin attacks involve a client from a different origin performing an action against the server. The malicious action is typically a GET request or a form POST (Cross-Site Request Forgery, CSRF), but opening a malicious WebSocket is also possible. Blazor apps offer the same guarantees that any other SignalR app using the hub protocol offer:

- Apps can be accessed cross-origin unless additional measures are taken to prevent it. To disable cross-origin access, either disable CORS in the endpoint by adding the CORS Middleware to the pipeline and adding the DisableCorsAttribute to the

Blazor endpoint metadata or limit the set of allowed origins by configuring SignalR for Cross-Origin Resource Sharing. For guidance on WebSocket origin restrictions, see WebSockets support in ASP.NET Core.

- If CORS is enabled, extra steps might be required to protect the app depending on the CORS configuration. If CORS is globally enabled, CORS can be disabled for the Blazor SignalR hub by adding the DisableCorsAttribute metadata to the endpoint metadata after calling MapBlazorHub on the endpoint route builder.

For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Click-jacking

Click-jacking involves rendering a site as an `<iframe>` inside a site from a different origin in order to trick the user into performing actions on the site under attack.

To protect an app from rendering inside of an `<iframe>`, use Content Security Policy (CSP) and the `X-Frame-Options` header.

For more information, see the following resources:

- Enforce a Content Security Policy for ASP.NET Core Blazor
- MDN web docs: X-Frame-Options

Open redirects

When an app session starts, the server performs basic validation of the URLs sent as part of starting the session. The framework checks that the base URL is a parent of the current URL before establishing the circuit. No additional checks are performed by the framework.

When a user selects a link on the client, the URL for the link is sent to the server, which determines what action to take. For example, the app may perform a client-side navigation or indicate to the browser to go to the new location.

Components can also trigger navigation requests programmatically through the use of NavigationManager. In such scenarios, the app might perform a client-side navigation or indicate to the browser to go to the new location.

Components must:

- Avoid using user input as part of the navigation call arguments.
- Validate arguments to ensure that the target is allowed by the app.

Otherwise, a malicious user can force the browser to go to a cyberattacker-controlled site. In this scenario, the cyberattacker tricks the app into using some user input as part of the invocation of the NavigationManager.NavigateTo method.

This advice also applies when rendering links as part of the app:

- If possible, use relative links.
- Validate that absolute link destinations are valid before including them in a page.

For more information, see Prevent open redirect attacks in ASP.NET Core.

Security checklist

The following list of security considerations isn't comprehensive:

- Validate arguments from events.
- Validate inputs and results from JS interop calls.
- Avoid using (or validate beforehand) user input for .NET to JS interop calls.
- Prevent the client from allocating an unbound amount of memory.
  - Data within the component.
  - DotNetObjectReference objects returned to the client.
- Protect against multiple dispatches.
- Cancel long-running operations when the component is disposed.
- Avoid events that produce large amounts of data.
- Avoid using user input as part of calls to NavigationManager.NavigateTo and validate user input for URLs against a set of allowed origins first if unavoidable.
- Don't make authorization decisions based on the state of the UI but only from component state.
- Consider using Content Security Policy (CSP) to protect against XSS attacks. For more information, see Enforce a Content Security Policy for ASP.NET Core Blazor.
- Consider using CSP and X-Frame-Options to protect against click-jacking.
- Ensure CORS settings are appropriate when enabling CORS or explicitly disable CORS for Blazor apps.
- Test to ensure that the server-side limits for the Blazor app provide an acceptable user experience without unacceptable levels of risk.

Account confirmation and password recovery in ASP.NET Core Blazor

Article • 10/08/2024

This article explains how to configure an ASP.NET Core Blazor Web App with email confirmation and password recovery.

Namespace

The app's namespace used by the example in this article is `BlazorSample`. Update the code examples to use the namespace of your app.

Select and configure an email provider

In this article, Mailchimp's Transactional API is used via Mandrill.net to send email. We recommend using an email service to send email rather than SMTP. SMTP is difficult to configure and secure properly. Whichever email service you use, access their guidance for .NET apps, create an account, configure an API key for their service, and install any NuGet packages required.

Create a class to fetch the secure email API key. The example in this article uses a class named `AuthMessageSenderOptions` with a `EmailAuthKey` property to hold the key.

`AuthMessageSenderOptions`:

C#

```
namespace BlazorSample;

public class AuthMessageSenderOptions
{
    public string? EmailAuthKey { get; set; }
}
```

Register the `AuthMessageSenderOptions` configuration instance in the `Program` file:

C#

```
builder.Services.Configure<AuthMessageSenderOptions>(builder.Configuration);
```

Configure a user secret for the provider's security key

Set the key with the Secret Manager tool. In the following example, the key name is `EmailAuthKey`, and the key is represented by the `{KEY}` placeholder. In a command shell, navigate to the app's root folder and execute the following command with the API key:

.NET CLI

```
dotnet user-secrets set "EmailAuthKey" "{KEY}"
```

For more information, see Safe storage of app secrets in development in ASP.NET Core.

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

Implement `IEmailSender`

Implement `IEmailSender` for the provider. The following example is based on Mailchimp's Transactional API using Mandrill.net. For a different provider, refer to their documentation on how to implement sending a message in the `Execute` method.

`Components/Account/EmailSender.cs`:

C#

```
using Microsoft.AspNetCore.Identity;
using Microsoft.Extensions.Options;
using Mandrill;
using Mandrill.Model;
using BlazorSample.Data;
```

```
namespace BlazorSample.Components.Account;

public class EmailSender(IOptions<AuthMessageSenderOptions> optionsAccessor,
    ILogger<EmailSender> logger) : IEmailSender<ApplicationUser>
{
    private readonly ILogger logger = logger;

    public AuthMessageSenderOptions Options { get; } =
optionsAccessor.Value;

    public Task SendConfirmationLinkAsync(ApplicationUser user, string
email,
        string confirmationLink) => SendEmailAsync(email, "Confirm your
email",
        "Please confirm your account by " +
        $"<a href='{confirmationLink}'>clicking here</a>.");

    public Task SendPasswordResetLinkAsync(ApplicationUser user, string
email,
        string resetLink) => SendEmailAsync(email, "Reset your password",
        $"Please reset your password by <a href='{resetLink}'>clicking
here</a>.");

    public Task SendPasswordResetCodeAsync(ApplicationUser user, string
email,
        string resetCode) => SendEmailAsync(email, "Reset your password",
        $"Please reset your password using the following code:
{resetCode}");

    public async Task SendEmailAsync(string toEmail, string subject, string
message)
    {
        if (string.IsNullOrEmpty(Options.EmailAuthKey))
        {
            throw new Exception("Null EmailAuthKey");
        }

        await Execute(Options.EmailAuthKey, subject, message, toEmail);
    }

    public async Task Execute(string apiKey, string subject, string message,
        string toEmail)
    {
        var api = new MandrillApi(apiKey);
        var mandrillMessage = new MandrillMessage("sarah@contoso.com",
toEmail,
            subject, message);
        await api.Messages.SendAsync(mandrillMessage);

        logger.LogInformation("Email to {EmailAddress} sent!", toEmail);
    }
}
```

> [!NOTE]
> Body content for messages might require special encoding for the email service provider. If links in the message body can't be followed, consult the service provider's documentation.

Configure app to support email

In the `Program` file, change the email sender implementation to the `EmailSender`:

diff

```
- builder.Services.AddSingleton<IEmailSender<ApplicationUser>,
IdentityNoOpEmailSender>();
+ builder.Services.AddSingleton<IEmailSender<ApplicationUser>, EmailSender>
();
```

Remove the `IdentityNoOpEmailSender` (`Components/Account/IdentityNoOpEmailSender.cs`) from the app.

In the `RegisterConfirmation` component (`Components/Account/Pages/RegisterConfirmation.razor`), remove the conditional block in the `@code` block that checks if the `EmailSender` is an `IdentityNoOpEmailSender`:

diff

```
- else if (EmailSender is IdentityNoOpEmailSender)
- {
-     ...
- }
```

Also in the `RegisterConfirmation` component, remove the Razor markup and code for checking the `emailConfirmationLink` field, leaving just the line instructing the user to check their email ...

diff

```
- @if (emailConfirmationLink is not null)
- {
-     ...
- }
- else
- {
      <p>Please check your email to confirm your account.</p>
```

```
- }

@code {
-    private string? emailConfirmationLink;

     ...
}
```

Email and activity timeout

The default inactivity timeout is 14 days. The following code sets the inactivity timeout to five days with sliding expiration:

C#

```
builder.Services.ConfigureApplicationCookie(options => {
    options.ExpireTimeSpan = TimeSpan.FromDays(5);
    options.SlidingExpiration = true;
});
```

Change all ASP.NET Core Data Protection token lifespans

The following code changes Data Protection tokens' timeout period to three hours:

C#

```
builder.Services.Configure<DataProtectionTokenProviderOptions>(options =>
    options.TokenLifespan = TimeSpan.FromHours(3));
```

The built in Identity user tokens (AspNetCore/src/Identity/Extensions.Core/src/TokenOptions.cs) have a one day timeout .

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205) .

Change the email token lifespan

The default token lifespan of the Identity user tokens is one day.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

To change the email token lifespan, add a custom DataProtectorTokenProvider<TUser> and DataProtectionTokenProviderOptions:

`CustomTokenProvider.cs`:

C#

```
using Microsoft.AspNetCore.DataProtection;
using Microsoft.AspNetCore.Identity;
using Microsoft.Extensions.Options;

namespace BlazorSample;

public class CustomEmailConfirmationTokenProvider<TUser>
    : DataProtectorTokenProvider<TUser> where TUser : class
{
    public CustomEmailConfirmationTokenProvider(
        IDataProtectionProvider dataProtectionProvider,
        IOptions<EmailConfirmationTokenProviderOptions> options,
        ILogger<DataProtectorTokenProvider<TUser>> logger)
        : base(dataProtectionProvider, options, logger)
    {
    }
}

public class EmailConfirmationTokenProviderOptions
    : DataProtectionTokenProviderOptions
{
    public EmailConfirmationTokenProviderOptions()
    {
        Name = "EmailDataProtectorTokenProvider";
        TokenLifespan = TimeSpan.FromHours(4);
    }
}

public class CustomPasswordResetTokenProvider<TUser>
    : DataProtectorTokenProvider<TUser> where TUser : class
```

```
{
    public CustomPasswordResetTokenProvider(
        IDataProtectionProvider dataProtectionProvider,
        IOptions<PasswordResetTokenProviderOptions> options,
        ILogger<DataProtectorTokenProvider<TUser>> logger)
        : base(dataProtectionProvider, options, logger)
    {
    }
}

public class PasswordResetTokenProviderOptions :
    DataProtectionTokenProviderOptions
{
    public PasswordResetTokenProviderOptions()
    {
        Name = "PasswordResetDataProtectorTokenProvider";
        TokenLifespan = TimeSpan.FromHours(3);
    }
}
```

Configure the services to use the custom token provider in the `Program` file:

C#

```
builder.Services.AddIdentityCore<ApplicationUser>(options =>
    {
        options.SignIn.RequireConfirmedAccount = true;
        options.Tokens.ProviderMap.Add("CustomEmailConfirmation",
            new TokenProviderDescriptor(

typeof(CustomEmailConfirmationTokenProvider<ApplicationUser>)));
        options.Tokens.EmailConfirmationTokenProvider =
            "CustomEmailConfirmation";
    })
    .AddEntityFrameworkStores<ApplicationDbContext>()
    .AddSignInManager()
    .AddDefaultTokenProviders();

builder.Services
    .AddTransient<CustomEmailConfirmationTokenProvider<ApplicationUser>>();
```

Troubleshoot

If you can't get email working:

- Set a breakpoint in `EmailSender.Execute` to verify `SendEmailAsync` is called.
- Create a console app to send email using code similar to `EmailSender.Execute` to debug the problem.
- Review the account email history pages at the email provider's website.

- Check your spam folder for messages.
- Try another email alias on a different email provider, such as Microsoft, Yahoo, or Gmail.
- Try sending to different email accounts.

> ⚠ **Warning**
>
> Do **not** use production secrets in test and development. If you publish the app to Azure, set secrets as application settings in the Azure Web App portal. The configuration system is set up to read keys from environment variables.

Enable account confirmation after a site has users

Enabling account confirmation on a site with users locks out all the existing users. Existing users are locked out because their accounts aren't confirmed. To work around existing user lockout, use one of the following approaches:

- Update the database to mark all existing users as confirmed.
- Confirm existing users. For example, batch-send emails with confirmation links.

Enable QR code generation for TOTP authenticator apps in an ASP.NET Core Blazor Web App

Article • 10/04/2024

This article explains how to configure an ASP.NET Core Blazor Web App with QR code generation for TOTP authenticator apps.

For an introduction to two-factor authentication (2FA) with authenticator apps using a Time-based One-time Password Algorithm (TOTP), see Enable QR code generation for TOTP authenticator apps in ASP.NET Core.

> ⚠ **Warning**
>
> An ASP.NET Core TOTP code should be kept secret because it can be used to authenticate successfully multiple times before it expires.

Scaffold the Enable Authenticator component into the app

Follow the guidance in Scaffold Identity in ASP.NET Core projects to scaffold `Pages\Manage\EnableAuthenticator` into the app.

> ⓘ **Note**
>
> Although only the `EnableAuthenticator` component is selected for scaffolding in this example, scaffolding currently adds all of the Identity components to the app. Additionally, exceptions may be thrown during the process of scaffolding into the app. If exceptions occur when database migrations occur, stop the app and restart the app on each exception. For more information, see Scaffolding exceptions for Blazor Web App (dotnet/Scaffolding #2694).

Be patient while migrations are executed. Depending on the speed of the system, it can take up to a minute or two for database migrations to finish.

For more information, see Scaffold Identity in ASP.NET Core projects. For guidance on using the .NET CLI instead of Visual Studio, see ASP.NET Core code generator tool

(`aspnet-codegenerator`).

Adding QR codes to the 2FA configuration page

These instructions use Shim Sangmin 's qrcode.js: Cross-browser QRCode generator for JavaScript (davidshimjs/qrcodejs GitHub repository).

Download the qrcode.min.js library to the `wwwroot` folder of the solution's server project. The library has no dependencies.

In the `App` component (`Components/App.razor`), place a library script reference after Blazor's <script> tag:

razor

```
<script src="qrcode.min.js"></script>
```

The `EnableAuthenticator` component, which is part of the QR code system in the app and displays the QR code to users, adopts static server-side rendering (static SSR) with enhanced navigation. Therefore, normal scripts can't execute when the component loads or updates under enhanced navigation. Extra steps are required to trigger the QR code to load in the UI when the page is loaded. To accomplish loading the QR code, the approach explained in ASP.NET Core Blazor JavaScript with static server-side rendering (static SSR) is adopted.

Add the following JavaScript initializer to the server project's `wwwroot` folder. The `{NAME}` placeholder must be the name of the app's assembly in order for Blazor to locate and load the file automatically. If the server app's assembly name is `BlazorSample`, the file is named `BlazorSample.lib.module.js`.

`wwwroot/{NAME}.lib.module.js`:

JavaScript

```
const pageScriptInfoBySrc = new Map();

function registerPageScriptElement(src) {
  if (!src) {
    throw new Error('Must provide a non-empty value for the "src"
attribute.');
  }

  let pageScriptInfo = pageScriptInfoBySrc.get(src);
```

```
  if (pageScriptInfo) {
    pageScriptInfo.referenceCount++;
  } else {
    pageScriptInfo = { referenceCount: 1, module: null };
    pageScriptInfoBySrc.set(src, pageScriptInfo);
    initializePageScriptModule(src, pageScriptInfo);
  }
}

function unregisterPageScriptElement(src) {
  if (!src) {
    return;
  }

  const pageScriptInfo = pageScriptInfoBySrc.get(src);

  if (!pageScriptInfo) {
    return;
  }

  pageScriptInfo.referenceCount--;
}

async function initializePageScriptModule(src, pageScriptInfo) {
  if (src.startsWith("./")) {
    src = new URL(src.substr(2), document.baseURI).toString();
  }

  const module = await import(src);

  if (pageScriptInfo.referenceCount <= 0) {
    return;
  }

  pageScriptInfo.module = module;
  module.onLoad?.();
  module.onUpdate?.();
}

function onEnhancedLoad() {
  for (const [src, { module, referenceCount }] of pageScriptInfoBySrc) {
    if (referenceCount <= 0) {
      module?.onDispose?.();
      pageScriptInfoBySrc.delete(src);
    }
  }

  for (const { module } of pageScriptInfoBySrc.values()) {
    module?.onUpdate?.();
  }
}

export function afterWebStarted(blazor) {
  customElements.define('page-script', class extends HTMLElement {
```

```
    static observedAttributes = ['src'];

    attributeChangedCallback(name, oldValue, newValue) {
      if (name !== 'src') {
        return;
      }

      this.src = newValue;
      unregisterPageScriptElement(oldValue);
      registerPageScriptElement(newValue);
    }

    disconnectedCallback() {
      unregisterPageScriptElement(this.src);
    }
  });

  blazor.addEventListener('enhancedload', onEnhancedLoad);
}
```

Add the following shared `PageScript` component to the server app.

`Components/PageScript.razor`:

razor

```
<page-script src="@Src"></page-script>

@code {
    [Parameter]
    [EditorRequired]
    public string Src { get; set; } = default!;
}
```

Add the following collocated JS file for the `EnableAuthenticator` component, which is located at `Components/Account/Pages/Manage/EnableAuthenticator.razor`. The `onLoad` function creates the QR code with Sangmin's `qrcode.js` library using the QR code URI produced by the `GenerateQrCodeUri` method in the component's `@code` block.

`Components/Account/Pages/Manage/EnableAuthenticator.razor.js`:

JavaScript

```
export function onLoad() {
  const uri = document.getElementById('qrCodeData').getAttribute('data-
url');
  new QRCode(document.getElementById('qrCode'), uri);
}
```

Under the `<PageTitle>` component in the `EnableAuthenticator` component, add the `PageScript` component with the path to the collocated JS file:

razor

```
<PageScript
Src="./Components/Account/Pages/Manage/EnableAuthenticator.razor.js" />
```

> **Note**
>
> An alternative to using the approach with the `PageScript` component is to use an event listener (`blazor.addEventListener("enhancedload", {CALLBACK})`) registered in an afterWebStarted JS initializer to listen for page updates caused by enhanced navigation. The callback (`{CALLBACK}` placeholder) performs the QR code initialization logic.
>
> Using the callback approach with `enhancedload`, the code executes for every enhanced navigation, even when the QR code `<div>` isn't rendered. Therefore, additional code must be added to check for the presence of the `<div>` before executing the code that adds a QR code.

Delete the `<div>` element that contains the QR code instructions:

diff

```
- <div class="alert alert-info">
-     Learn how to <a href="https://go.microsoft.com/fwlink/?
Linkid=852423">enable
-     QR code generation</a>.
- </div>
```

Locate the two `<div>` elements where the QR code should appear and where the QR code data is stored in the page.

Make the following changes:

- For the empty `<div>`, give the element an `id` of `qrCode`.
- For the `<div>` with the `data-url` attribute, give the element an `id` of `qrCodeData`.

diff

```
- <div></div>
- <div data-url="@authenticatorUri"></div>
```

```
+ <div id="qrCode"></div>
+ <div id="qrCodeData" data-url="@authenticatorUri"></div>
```

Change the site name in the `GenerateQrCodeUri` method of the `EnableAuthenticator` component. The default value is `Microsoft.AspNetCore.Identity.UI`. Change the value to a meaningful site name that users can identify easily in their authenticator app. Developers usually set a site name that matches the company's name. Examples: Yahoo, Amazon, Etsy, Microsoft, Zoho. We recommend limiting the site name length to 30 characters or less to allow the site name to display on narrow mobile device screens.

In the following example, the default value `Microsoft.AspNetCore.Identity.UI` is changed to the company name `Weyland-Yutani Corporation` (©1986 20th Century Studios *Aliens*).

In the `GenerateQrCodeUri` method:

diff

```
- UrlEncoder.Encode("Microsoft.AspNetCore.Identity.UI"),
+ UrlEncoder.Encode("Weyland-Yutani Corporation"),
```

Run the app and ensure that the QR code is scannable and that the code validates.

> ⚠ **Warning**
>
> An ASP.NET Core TOTP code should be kept secret because it can be used to authenticate successfully multiple times before it expires.

`EnableAuthenticator` component in reference source

The `EnableAuthenticator` component can be inspected in reference source:

EnableAuthenticator component in reference source

> ⓘ **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list.

For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Server-side ASP.NET Core Blazor additional security scenarios

Article • 10/04/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to configure server-side Blazor for additional security scenarios, including how to pass tokens to a Blazor app.

> **Note**
>
> The code examples in this article adopt nullable reference types (NRTs) and .NET compiler null-state static analysis, which are supported in ASP.NET Core in .NET 6 or later. When targeting ASP.NET Core 5.0 or earlier, remove the null type designation (`?`) from the `string?`, `TodoItem[]?`, `WeatherForecast[]?`, and `IEnumerable<GitHubBranch>?` types in the article's examples.

Pass tokens to a server-side Blazor app

Updating this section for Blazor Web Apps is pending Update section on passing tokens in Blazor Web Apps (dotnet/AspNetCore.Docs #31691). For more information, see Problem providing Access Token to HttpClient in Interactive Server mode (dotnet/aspnetcore #52390).

For Blazor Server, view the 7.0 version of this article section.

Set the authentication scheme

For an app that uses more than one Authentication Middleware and thus has more than one authentication scheme, the scheme that Blazor uses can be explicitly set in the endpoint configuration of the `Program` file. The following example sets the OpenID Connect (OIDC) scheme:

C#

```
using Microsoft.AspNetCore.Authentication.OpenIdConnect;

...

app.MapRazorComponents<App>().RequireAuthorization(
    new AuthorizeAttribute
    {
        AuthenticationSchemes = OpenIdConnectDefaults.AuthenticationScheme
    })
    .AddInteractiveServerRenderMode();
```

Circuit handler to capture users for custom services

Use a CircuitHandler to capture a user from the AuthenticationStateProvider and set the user in a service. If you want to update the user, register a callback to AuthenticationStateChanged and enqueue a Task to obtain the new user and update the service. The following example demonstrates the approach.

In the following example:

- OnConnectionUpAsync is called every time the circuit reconnects, setting the user for the lifetime of the connection. Only the OnConnectionUpAsync method is required unless you implement updates via a handler for authentication changes (`AuthenticationChanged` in the following example).
- OnCircuitOpenedAsync is called to attach the authentication changed handler, `AuthenticationChanged`, to update the user.
- The `catch` block of the `UpdateAuthentication` task takes no action on exceptions because there's no way to report the exceptions at this point in code execution. If an exception is thrown from the task, the exception is reported elsewhere in app.

`UserService.cs`:

C#

```
using System.Security.Claims;
using Microsoft.AspNetCore.Components.Authorization;
using Microsoft.AspNetCore.Components.Server.Circuits;

public class UserService
{
    private ClaimsPrincipal currentUser = new(new ClaimsIdentity());
```

```
    public ClaimsPrincipal GetUser() => currentUser;

    internal void SetUser(ClaimsPrincipal user)
    {
        if (currentUser != user)
        {
            currentUser = user;
        }
    }
}

internal sealed class UserCircuitHandler(
        AuthenticationStateProvider authenticationStateProvider,
        UserService userService)
        : CircuitHandler, IDisposable
{
    public override Task OnCircuitOpenedAsync(Circuit circuit,
        CancellationToken cancellationToken)
    {
        authenticationStateProvider.AuthenticationStateChanged +=
            AuthenticationChanged;

        return base.OnCircuitOpenedAsync(circuit, cancellationToken);
    }

    private void AuthenticationChanged(Task<AuthenticationState> task)
    {
        _ = UpdateAuthentication(task);

        async Task UpdateAuthentication(Task<AuthenticationState> task)
        {
            try
            {
                var state = await task;
                userService.SetUser(state.User);
            }
            catch
            {
            }
        }
    }

    public override async Task OnConnectionUpAsync(Circuit circuit,
        CancellationToken cancellationToken)
    {
        var state = await
authenticationStateProvider.GetAuthenticationStateAsync();
        userService.SetUser(state.User);
    }

    public void Dispose()
    {
        authenticationStateProvider.AuthenticationStateChanged -=
            AuthenticationChanged;
```

```
    }
}
```

In the `Program` file:

C#

```
using Microsoft.AspNetCore.Components.Server.Circuits;
using Microsoft.Extensions.DependencyInjection.Extensions;

...

builder.Services.AddScoped<UserService>();
builder.Services.TryAddEnumerable(
    ServiceDescriptor.Scoped<CircuitHandler, UserCircuitHandler>());
```

Use the service in a component to obtain the user:

razor

```
@inject UserService UserService

<h1>Hello, @(UserService.GetUser().Identity?.Name ?? "world")!</h1>
```

To set the user in middleware for MVC, Razor Pages, and in other ASP.NET Core scenarios, call `SetUser` on the `UserService` in custom middleware after the Authentication Middleware runs, or set the user with an IClaimsTransformation implementation. The following example adopts the middleware approach.

`UserServiceMiddleware.cs`:

C#

```
public class UserServiceMiddleware
{
    private readonly RequestDelegate next;

    public UserServiceMiddleware(RequestDelegate next)
    {
        this.next = next ?? throw new ArgumentNullException(nameof(next));
    }

    public async Task InvokeAsync(HttpContext context, UserService service)
    {
        service.SetUser(context.User);
        await next(context);
    }
}
```

Immediately before the call to `app.MapRazorComponents<App>()` in the `Program` file, call the middleware:

```
C#

app.UseMiddleware<UserServiceMiddleware>();
```

Access `AuthenticationStateProvider` in outgoing request middleware

The AuthenticationStateProvider from a DelegatingHandler for HttpClient created with IHttpClientFactory can be accessed in outgoing request middleware using a circuit activity handler.

> **Note**
>
> For general guidance on defining delegating handlers for HTTP requests by HttpClient instances created using IHttpClientFactory in ASP.NET Core apps, see the following sections of Make HTTP requests using IHttpClientFactory in ASP.NET Core:
>
> - Outgoing request middleware
> - Use DI in outgoing request middleware

The following example uses AuthenticationStateProvider to attach a custom user name header for authenticated users to outgoing requests.

First, implement the `CircuitServicesAccessor` class in the following section of the Blazor dependency injection (DI) article:

Access server-side Blazor services from a different DI scope

Use the `CircuitServicesAccessor` to access the AuthenticationStateProvider in the DelegatingHandler implementation.

`AuthenticationStateHandler.cs`:

```
C#

public class AuthenticationStateHandler(
    CircuitServicesAccessor circuitServicesAccessor)
    : DelegatingHandler
```

```
{
    protected override async Task<HttpResponseMessage> SendAsync(
        HttpRequestMessage request, CancellationToken cancellationToken)
    {
        var authStateProvider = circuitServicesAccessor.Services
            .GetRequiredService<AuthenticationStateProvider>();
        var authState = await
authStateProvider.GetAuthenticationStateAsync();
        var user = authState.User;

        if (user.Identity is not null && user.Identity.IsAuthenticated)
        {
            request.Headers.Add("X-USER-IDENTITY-NAME", user.Identity.Name);
        }

        return await base.SendAsync(request, cancellationToken);
    }
}
```

In the `Program` file, register the `AuthenticationStateHandler` and add the handler to the IHttpClientFactory that creates HttpClient instances:

C#

```
builder.Services.AddTransient<AuthenticationStateHandler>();

builder.Services.AddHttpClient("HttpMessageHandler")
    .AddHttpMessageHandler<AuthenticationStateHandler>();
```

Secure ASP.NET Core Blazor WebAssembly

Article • 09/27/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

Blazor WebAssembly apps are secured in the same manner as single-page applications (SPAs). There are several approaches for authenticating users to SPAs, but the most common and comprehensive approach is to use an implementation based on the OAuth 2.0 protocol, such as OpenID Connect (OIDC).

The Blazor WebAssembly security documentation primarily focuses on how to accomplish user authentication and authorization tasks. For OAuth 2.0/OIDC general concept coverage, see the resources in the main overview article's *Additional resources* section.

Client-side/SPA security of sensitive data and credentials

A Blazor WebAssembly app's .NET/C# codebase is served to clients, and the app's code can't be protected from inspection and tampering by users. Never place credentials or secrets into a Blazor WebAssembly app, such as app secrets, connection strings, passwords, private .NET/C# code, or other sensitive data.

To protect .NET/C# code and use ASP.NET Core Data Protection features to secure data, use a server-side ASP.NET Core web API. Have the client-side Blazor WebAssembly app call the server-side web API for secure app features and data processing. For more information, see Call a web API from an ASP.NET Core Blazor app and the articles in this node.

For local development testing, the Secret Manager tool is recommended for securing sensitive data.

Authentication library

Blazor WebAssembly supports authenticating and authorizing apps using OIDC via the Microsoft.AspNetCore.Components.WebAssembly.Authentication library using the Microsoft identity platform. The library provides a set of primitives for seamlessly authenticating against ASP.NET Core backends. The library can authenticate against any third-party Identity Provider (IP) that supports OIDC, which are called OpenID Providers (OP).

The authentication support in the Blazor WebAssembly Library (`Authentication.js`) is built on top of the Microsoft Authentication Library (MSAL, msal.js), which is used to handle the underlying authentication protocol details. The Blazor WebAssembly Library only supports the Proof Key for Code Exchange (PKCE) authorization code flow. Implicit grant isn't supported.

Other options for authenticating SPAs exist, such as the use of SameSite cookies. However, the engineering design of Blazor WebAssembly uses OAuth and OIDC as the best option for authentication in Blazor WebAssembly apps. Token-based authentication based on JSON Web Tokens (JWTs) was chosen over cookie-based authentication for functional and security reasons:

- Using a token-based protocol offers fewer vulnerabilities, as the tokens aren't sent in all requests.
- The tokens are explicitly sent to the server, so server endpoints don't require protection against Cross-Site Request Forgery (CSRF). This allows you to host Blazor WebAssembly apps alongside MVC or Razor pages apps.
- Tokens have narrower permissions than cookies. For example, tokens can't be used to manage the user account or change a user's password unless such functionality is explicitly implemented.
- Tokens have a short lifetime, one hour, which limits the attack window. Tokens can also be revoked at any time.
- Self-contained JWTs offer guarantees to the client and server about the authentication process. For example, a client has the means to detect and validate that the tokens it receives are legitimate and were emitted as part of a given authentication process. If a third party attempts to switch a token in the middle of the authentication process, the client can detect the switched token and avoid using it.
- Tokens with OAuth and OIDC don't rely on the user agent behaving correctly to ensure that the app is secure.
- Token-based protocols, such as OAuth and OIDC, allow for authenticating and authorizing users in standalone Blazor Webassembly apps with the same set of

security characteristics.

> **Important**
>
> For versions of ASP.NET Core that adopt Duende Identity Server in Blazor project templates, Duende Software might require you to pay a license fee for production use of Duende Identity Server. For more information, see Migrate from ASP.NET Core 5.0 to 6.0.

Authentication process with OIDC

The Microsoft.AspNetCore.Components.WebAssembly.Authentication library offers several primitives to implement authentication and authorization using OIDC. In broad terms, authentication works as follows:

- When an anonymous user selects the login button or requests a Razor component or page with the [Authorize] attribute applied, the user is redirected to the app's login page (`/authentication/login`).
- In the login page, the authentication library prepares for a redirect to the authorization endpoint. The authorization endpoint is outside of the Blazor WebAssembly app and can be hosted at a separate origin. The endpoint is responsible for determining whether the user is authenticated and for issuing one or more tokens in response. The authentication library provides a login callback to receive the authentication response.
  - If the user isn't authenticated, the user is redirected to the underlying authentication system, which is usually ASP.NET Core Identity.
  - If the user was already authenticated, the authorization endpoint generates the appropriate tokens and redirects the browser back to the login callback endpoint (`/authentication/login-callback`).
- When the Blazor WebAssembly app loads the login callback endpoint (`/authentication/login-callback`), the authentication response is processed.
  - If the authentication process completes successfully, the user is authenticated and optionally sent back to the original protected URL that the user requested.
  - If the authentication process fails for any reason, the user is sent to the login failed page (`/authentication/login-failed`), where an error is displayed.

`Authentication` component

The `Authentication` component (`Authentication.razor`) handles remote authentication operations and permits the app to:

- Configure app routes for authentication states.
- Set UI content for authentication states.
- Manage authentication state.

Authentication actions, such as registering or signing in a user, are passed to the Blazor framework's RemoteAuthenticatorViewCore<TAuthenticationState> component, which persists and controls state across authentication operations.

For more information and examples, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Authorization

In Blazor WebAssembly apps, authorization checks can be bypassed because all client-side code can be modified by users. The same is true for all client-side app technologies, including JavaScript SPA frameworks or native apps for any operating system.

Always perform authorization checks on the server within any API endpoints accessed by your client-side app.

Customize authentication

Blazor WebAssembly provides methods to add and retrieve additional parameters for the underlying Authentication library to conduct remote authentication operations with external identity providers.

To pass additional parameters, NavigationManager supports passing and retrieving history entry state when performing external location changes. For more information, see the following resources:

- Blazor *Fundamentals* > *Routing and navigation* article
  - Navigation history state
  - Navigation options
- MDN documentation: History API

The state stored by the History API provides the following benefits for remote authentication:

- The state passed to the secured app endpoint is tied to the navigation performed to authenticate the user at the `authentication/login` endpoint.

- Extra work encoding and decoding data is avoided.
- Vulnerabilities are reduced. Unlike using the query string to store navigation state, a top-level navigation or influence from a different origin can't set the state stored by the History API.
- The history entry is replaced upon successful authentication, so the state attached to the history entry is removed and doesn't require clean up.

InteractiveRequestOptions represents the request to the identity provider for logging in or provisioning an access token.

NavigationManagerExtensions provides the NavigateToLogin method for a login operation and NavigateToLogout for a logout operation. The methods call NavigationManager.NavigateTo, setting the history entry state with a passed InteractiveRequestOptions or a new InteractiveRequestOptions instance created by the method for:

- A user signing in (InteractionType.SignIn) with the current URI for the return URL.
- A user signing out (InteractionType.SignOut) with the return URL.

The following authentication scenarios are covered in the ASP.NET Core Blazor WebAssembly additional security scenarios article:

- Customize the login process
- Logout with a custom return URL
- Customize options before obtaining a token interactively
- Customize options when using an IAccessTokenProvider
- Obtain the login path from authentication options

Require authorization for the entire app

Apply the [Authorize] attribute (API documentation) to each Razor component of the app using ***one*** of the following approaches:

- In the app's Imports file, add an @using directive for the Microsoft.AspNetCore.Authorization namespace with an @attribute directive for the [Authorize] attribute.

  `_Imports.razor`:

  razor

  ```
  @using Microsoft.AspNetCore.Authorization
  @attribute [Authorize]
  ```

Allow anonymous access to the `Authentication` component to permit redirection to the identity provider. Add the following Razor code to the `Authentication` component under its @page directive.

`Authentication.razor`:

```razor
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@attribute [AllowAnonymous]
```

- Add the attribute to each Razor component under the @page directive:

```razor
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize]
```

> ⓘ Note
>
> Setting an AuthorizationOptions.FallbackPolicy to a policy with RequireAuthenticatedUser is **not** supported.

Use one identity provider app registration per app

Some of the articles under this *Overview* pertain to Blazor hosting scenarios that involve two or more apps. A standalone Blazor WebAssembly app uses web API with authenticated users to access server resources and data provided by a server app.

When this scenario is implemented in documentation examples, ***two*** identity provider registrations are used, one for the client app and one for the server app. Using separate registrations, for example in Microsoft Entra ID, isn't strictly required. However, using two registrations is a security best practice because it isolates the registrations by app. Using separate registrations also allows independent configuration of the client and server registrations.

Refresh tokens

Although refresh tokens can't be secured in Blazor WebAssembly apps, they can be used if you implement them with appropriate security strategies.

For standalone Blazor WebAssembly apps in ASP.NET Core in .NET 6 or later, we recommend using:

- The OAuth 2.0 Authorization Code flow (Code) with Proof Key for Code Exchange (PKCE).
- A refresh token that has a short expiration.
- A rotated refresh token.
- A refresh token with an expiration after which a new interactive authorization flow is required to refresh the user's credentials.

For more information, see the following resources:

- Microsoft identity platform refresh tokens: Refresh token lifetime
- OAuth 2.0 for Browser-Based Apps (IETF specification)

Establish claims for users

Apps often require claims for users based on a web API call to a server. For example, claims are frequently used to establish authorization in an app. In these scenarios, the app requests an access token to access the service and uses the token to obtain user data for creating claims.

For examples, see the following resources:

- Additional scenarios: Customize the user
- ASP.NET Core Blazor WebAssembly with Microsoft Entra ID groups and roles

Prerendering support

Prerendering isn't supported for authentication endpoints (`/authentication/` path segment).

For more information, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Azure App Service on Linux with Identity Server

Specify the issuer explicitly when deploying to Azure App Service on Linux with Identity Server.

For more information, see Use Identity to secure a Web API backend for SPAs.

Windows Authentication

We don't recommend using Windows Authentication with Blazor Webassembly or with any other SPA framework. We recommend using token-based protocols instead of Windows Authentication, such as OIDC with Active Directory Federation Services (ADFS).

If Windows Authentication is used with Blazor Webassembly or with any other SPA framework, additional measures are required to protect the app from cross-site request forgery (CSRF) tokens. The same concerns that apply to cookies apply to Windows Authentication with the addition that Windows Authentication doesn't offer a mechanism to prevent sharing of the authentication context across origins. Apps using Windows Authentication without additional protection from CSRF should at least be restricted to an organization's intranet and not be used on the open Internet.

For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Secure a SignalR hub

To secure a SignalR hub in the server API project, apply the [Authorize] attribute to the hub class or to methods of the hub class.

In a client project with prerendering, such as hosted Blazor WebAssembly (ASP.NET Core in .NET 7 or earlier) or a Blazor Web App (ASP.NET Core in .NET 8 or later), see the guidance in ASP.NET Core Blazor SignalR guidance.

In a client project component without prerendering, such as standalone Blazor WebAssembly, or non-browser apps, supply an access token to the hub connection, as the following example demonstrates. For more information, see Authentication and authorization in ASP.NET Core SignalR.

razor

```
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject IAccessTokenProvider TokenProvider
@inject NavigationManager Navigation

...

var tokenResult = await TokenProvider.RequestAccessToken();

if (tokenResult.TryGetToken(out var token))
```

```
{
    hubConnection = new HubConnectionBuilder()
        .WithUrl(Navigation.ToAbsoluteUri("/chathub"),
            options => { options.AccessTokenProvider = () =>
Task.FromResult(token?.Value); })
        .Build();

  ...
}
```

Logging

This section applies to Blazor WebAssembly apps in ASP.NET Core in .NET 7 or later.

To enable debug or trace logging, see the *Authentication logging (Blazor WebAssembly)* section in a 7.0 or later version of the ASP.NET Core Blazor logging article.

The WebAssembly sandbox

The WebAssembly *sandbox* restricts access to the environment of the system executing WebAssembly code, including access to I/O subsystems, system storage and resources, and the operating system. The isolation between WebAssembly code and the system that executes the code makes WebAssembly a safe coding framework for systems. However, WebAssembly is vulnerable to side-channel attacks at the hardware level. Normal precautions and due diligence in sourcing hardware and placing limitations on accessing hardware apply.

WebAssembly isn't owned or maintained by Microsoft.

For more information, see the following W3C resources:

- WebAssembly: Security
- WebAssembly Specification: Security Considerations
- W3C WebAssembly Community Group: Feedback and issues : The W3C WebAssembly Community Group link is only provided for reference, making it clear that WebAssembly security vulnerabilities and bugs are patched on an ongoing basis, often reported and addressed by browser. ***Don't send feedback or bug reports on Blazor to the W3C WebAssembly Community Group.*** Blazor feedback should be reported to the Microsoft ASP.NET Core product unit . If the Microsoft product unit determines that an underlying problem with WebAssembly exists, they take the appropriate steps to report the problem to the W3C WebAssembly Community Group.

Implementation guidance

Articles under this *Overview* provide information on authenticating users in Blazor WebAssembly apps against specific providers.

Standalone Blazor WebAssembly apps:

- General guidance for OIDC providers and the WebAssembly Authentication Library
- Microsoft Accounts
- Microsoft Entra ID (ME-ID)
- Azure Active Directory (AAD) B2C

Further configuration guidance is found in the following articles:

- ASP.NET Core Blazor WebAssembly additional security scenarios
- Use Graph API with ASP.NET Core Blazor WebAssembly

Use the Authorization Code flow with PKCE

Microsoft identity platform's Microsoft Authentication Library for JavaScript (MSAL) v2.0 or later provides support for the Authorization Code flow with Proof Key for Code Exchange (PKCE) and Cross-Origin Resource Sharing (CORS) for single-page applications, including Blazor.

Microsoft doesn't recommend using Implicit grant.

For more information, see the following resources:

- Authentication flow support in MSAL: Implicit grant
- Microsoft identity platform and implicit grant flow: Prefer the auth code flow
- Microsoft identity platform and OAuth 2.0 authorization code flow

Additional resources

- Microsoft identity platform documentation
  - General documentation
  - Access tokens
- Configure ASP.NET Core to work with proxy servers and load balancers
  - Using Forwarded Headers Middleware to preserve HTTPS scheme information across proxy servers and internal networks.
  - Additional scenarios and use cases, including manual scheme configuration, request path changes for correct request routing, and forwarding the request

scheme for Linux and non-IIS reverse proxies.

- Prerendering with authentication
- WebAssembly: Security
- WebAssembly Specification: Security Considerations

Secure ASP.NET Core Blazor WebAssembly with ASP.NET Core Identity

Article • 11/06/2024

Standalone Blazor WebAssembly apps can be secured with ASP.NET Core Identity by following the guidance in this article.

Endpoints for registering, logging in, and logging out

Instead of using the default UI provided by ASP.NET Core Identity for SPA and Blazor apps, which is based on Razor Pages, call MapIdentityApi in a backend API to add JSON API endpoints for registering and logging in users with ASP.NET Core Identity. Identity API endpoints also support advanced features, such as two-factor authentication and email verification.

On the client, call the `/register` endpoint to register a user with their email address and password:

C#

```
var result = await _httpClient.PostAsJsonAsync(
    "register", new
    {
        email,
        password
    });
```

On the client, log in a user with cookie authentication using the `/login` endpoint with `useCookies` query string set to `true`:

C#

```
var result = await _httpClient.PostAsJsonAsync(
    "login?useCookies=true", new
    {
        email,
        password
    });
```

The backend server API establishes cookie authentication with a call to AddIdentityCookies on the authentication builder:

```
C#

builder.Services
    .AddAuthentication(IdentityConstants.ApplicationScheme)
    .AddIdentityCookies();
```

Token authentication

For native and mobile scenarios where some clients don't support cookies, the login API provides a parameter to request tokens.

> ⚠ **Warning**
>
> We recommend using cookies for browser-based apps instead of tokens because the browser handles cookies without exposing them to JavaScript. If you opt to use token-based security in web apps, you're responsible for ensuring the tokens are kept secure.

A custom token (one that is proprietary to the ASP.NET Core Identity platform) is issued that can be used to authenticate subsequent requests. The token should be passed in the `Authorization` header as a bearer token. A refresh token is also provided. This token allows the app to request a new token when the old one expires without forcing the user to log in again.

The tokens are not standard JSON Web Tokens (JWTs). The use of custom tokens is intentional, as the built-in Identity API is meant primarily for simple scenarios. The token option is not intended to be a fully-featured identity service provider or token server, but instead an alternative to the cookie option for clients that can't use cookies.

The following guidance begins the process of implementing token-based authentication with the login API. Custom code is required to complete the implementation. For more information, see Use Identity to secure a Web API backend for SPAs.

Instead of the backend server API establishing cookie authentication with a call to AddIdentityCookies on the authentication builder, the server API sets up bearer token auth with the AddBearerToken extension method. Specify the scheme for bearer authentication tokens with IdentityConstants.BearerScheme.

In `Backend/Program.cs`, change the authentication services and configuration to the following:

C#

```
builder.Services
    .AddAuthentication()
    .AddBearerToken(IdentityConstants.BearerScheme);
```

In `BlazorWasmAuth/Identity/CookieAuthenticationStateProvider.cs`, remove the `useCookies` query string parameter in the `LoginAsync` method of the `CookieAuthenticationStateProvider`:

diff

```
- login?useCookies=true
+ login
```

At this point, you must provide custom code to parse the AccessTokenResponse on the client and manage the access and refresh tokens. For more information, see Use Identity to secure a Web API backend for SPAs.

Additional Identity scenarios

For additional Identity scenarios provided by the API, see Use Identity to secure a Web API backend for SPAs:

- Secure selected endpoints
- Token authentication
- Two-factor authentication (2FA)
- Recovery codes
- User info management

Use secure authentication flows to maintain sensitive data and credentials

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production

environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

Sample apps

In this article, sample apps serve as a reference for standalone Blazor WebAssembly apps that access ASP.NET Core Identity through a backend web API. The demonstration includes two apps:

- `Backend`: A backend web API app that maintains a user identity store for ASP.NET Core Identity.
- `BlazorWasmAuth`: A standalone Blazor WebAssembly frontend app with user authentication.

Access the sample apps through the latest version folder from the repository's root with the following link. The samples are provided for .NET 8 or later. See the `README` file in the `BlazorWebAssemblyStandaloneWithIdentity` folder for steps on how to run the sample apps.

View or download sample code (how to download)

Backend web API app packages and code

The backend web API app maintains a user identity store for ASP.NET Core Identity.

Packages

The app uses the following NuGet packages:

- Microsoft.AspNetCore.Identity.EntityFrameworkCore
- Microsoft.EntityFrameworkCore.InMemory
- NSwag.AspNetCore

If your app is to use a different EF Core database provider than the in-memory provider, don't create a package reference in your app for `Microsoft.EntityFrameworkCore.InMemory`.

In the app's project file (`.csproj`), invariant globalization is configured.

Sample app code

App settings configure backend and frontend URLs:

- `Backend` app (`BackendUrl`): `https://localhost:7211`
- `BlazorWasmAuth` app (`FrontendUrl`): `https://localhost:7171`

The Backend.http file can be used for testing the weather data request. Note that the `BlazorWasmAuth` app must be running to test the endpoint, and the endpoint is hardcoded into the file. For more information, see Use .http files in Visual Studio 2022.

The following setup and configuration is found in the app's Program file.

User identity with cookie authentication is added by calling AddAuthentication and AddIdentityCookies. Services for authorization checks are added by a call to AddAuthorizationBuilder.

Only recommended for demonstrations, the app uses the EF Core in-memory database provider for the database context registration (AddDbContext). The in-memory database provider makes it easy to restart the app and test the registration and login user flows. Each run starts with a fresh database, but the app includes test user seeding demonstration code, which is described later in this article. If the database is changed to SQLite, users are saved between sessions, but the database must be created through migrations, as shown in the EF Core getting started tutorial†. You can use other relational providers such as SQL Server for your production code.

> **Note**
>
> †The EF Core getting started tutorial uses PowerShell commands to execute database migrations when using Visual Studio. An alternative approach in Visual Studio is to use the Connected Services UI:
>
> In **Solution Explorer**, double-click **Connected Services**. In **Service Dependencies** > **SQL Server Express LocalDB**, select the ellipsis (`...`) followed by either **Add migration** to create a migration or **Update database** to update the database.

Configure Identity to use the EF Core database and expose the Identity endpoints via the calls to AddIdentityCore, AddEntityFrameworkStores, and AddApiEndpoints.

A Cross-Origin Resource Sharing (CORS) policy is established to permit requests from the frontend and backend apps. Fallback URLs are configured for the CORS policy if app settings don't provide them:

- `Backend` app (`BackendUrl`): `https://localhost:5001`
- `BlazorWasmAuth` app (`FrontendUrl`): `https://localhost:5002`

Services and endpoints for Swagger/OpenAPI are included for web API documentation and development testing. For more information on NSwag, see Get started with NSwag and ASP.NET Core.

User role claims are sent from a Minimal API at the `/roles` endpoint.

Routes are mapped for Identity endpoints by calling `MapIdentityApi<AppUser>()`.

A logout endpoint (`/Logout`) is configured in the middleware pipeline to sign users out.

To secure an endpoint, add the RequireAuthorization extension method to the route definition. For a controller, add the [Authorize] attribute to the controller or action.

For more information on basic patterns for initialization and configuration of a DbContext instance, see DbContext Lifetime, Configuration, and Initialization in the EF Core documentation.

Frontend standalone Blazor WebAssembly app packages and code

A standalone Blazor WebAssembly frontend app demonstrates user authentication and authorization to access a private webpage.

Packages

The app uses the following NuGet packages:

- Microsoft.AspNetCore.Components.WebAssembly.Authentication
- Microsoft.Extensions.Http
- Microsoft.AspNetCore.Components.WebAssembly
- Microsoft.AspNetCore.Components.WebAssembly.DevServer

Sample app code

The `Models` folder contains the app's models:

- FormResult (Identity/Models/FormResult.cs): Response for login and registration.
- UserInfo (Identity/Models/UserInfo.cs): User info from identity endpoint to establish claims.

The IAccountManagement interface (Identity/CookieHandler.cs) provides account management services.

The CookieAuthenticationStateProvider class (Identity/CookieAuthenticationStateProvider.cs) handles state for cookie-based authentication and provides account management service implementations described by the `IAccountManagement` interface. The `LoginAsync` method explicitly enables cookie authentication via the `useCookies` query string value of `true`. The class also manages creating role claims for authenticated users.

The CookieHandler class (Identity/CookieHandler.cs) ensures cookie credentials are sent with each request to the backend web API, which handles Identity and maintains the Identity data store.

The wwwroot/appsettings.file provides backend and frontend URL endpoints.

The App component exposes the authentication state as a cascading parameter. For more information, see ASP.NET Core Blazor authentication and authorization.

The MainLayout component and NavMenu component use the AuthorizeView component to selectively display content based on the user's authentication status.

The following components handle common user authentication tasks, making use of `IAccountManagement` services:

- Register component (Components/Identity/Register.razor)
- Login component (Components/Identity/Login.razor)
- Logout component (Components/Identity/Logout.razor)

The PrivatePage component (Components/Pages/PrivatePage.razor) requires authentication and shows the user's claims.

Services and configuration is provided in the Program file (Program.cs):

- The cookie handler is registered as a scoped service.
- Authorization services are registered.
- The custom authentication state provider is registered as a scoped service.
- The account management interface (`IAccountManagement`) is registered.
- The base host URL is configured for a registered HTTP client instance.

- The base backend URL is configured for a registered HTTP client instance that's used for auth interactions with the backend web API. The HTTP client uses the cookie handler to ensure that cookie credentials are sent with each request.

Call AuthenticationStateProvider.NotifyAuthenticationStateChanged when the user's authentication state changes. For an example, see the `LoginAsync` and `LogoutAsync` methods of the CookieAuthenticationStateProvider class (Identity/CookieAuthenticationStateProvider.cs).

> ⚠ **Warning**
>
> The **AuthorizeView** component selectively displays UI content depending on whether the user is authorized. All content within a Blazor WebAssembly app placed in an **AuthorizeView** component is discoverable without authentication, so sensitive content should be obtained from a backend server-based web API after authentication succeeds. For more information, see the following resources:
>
> - ASP.NET Core Blazor authentication and authorization
> - Call a web API from an ASP.NET Core Blazor app
> - ASP.NET Core Blazor WebAssembly additional security scenarios

Test user seeding demonstration

The `SeedData` class (SeedData.cs) demonstrates how to create test users for development. The test user, named Leela, signs into the app with the email address `leela@contoso.com`. The user's password is set to `Passw0rd!`. Leela is given `Administrator` and `Manager` roles for authorization, which enables the user to access the manager page at `/private-manager-page` but not the editor page at `/private-editor-page`.

> ⚠ **Warning**
>
> Never allow test user code to run in a production environment. `SeedData.InitializeAsync` is only called in the `Development` environment in the `Program` file:

C#

```
if (builder.Environment.IsDevelopment())
{
    await using var scope = app.Services.CreateAsyncScope();
```

```
    await SeedData.InitializeAsync(scope.ServiceProvider);
}
```

Roles

Due to a framework design issue (dotnet/aspnetcore #50037), role claims aren't sent back from the `manage/info` endpoint to create user claims for users of the `BlazorWasmAuth` app. Role claims are managed independently via a separate request in the `GetAuthenticationStateAsync` method of the CookieAuthenticationStateProvider class (Identity/CookieAuthenticationStateProvider.cs) after the user is authenticated in the `Backend` project.

In the `CookieAuthenticationStateProvider`, a roles request is made to the `/roles` endpoint of the `Backend` server API project. The response is read into a string by calling ReadAsStringAsync(). JsonSerializer.Deserialize deserializes the string into a custom `RoleClaim` array. Finally, the claims are added to the user's claims collection.

In the `Backend` server API's `Program` file, a Minimal API manages the `/roles` endpoint. Claims of RoleClaimType are selected into an anonymous type and serialized for return to the `BlazorWasmAuth` project with TypedResults.Json.

The roles endpoint requires authorization by calling RequireAuthorization. If you decide not to use Minimal APIs in favor of controllers for secure server API endpoints, be sure to set the [Authorize] attribute on controllers or actions.

Cross-domain hosting (same-site configuration)

The sample apps are configured for hosting both apps at the same domain. If you host the `Backend` app at a different domain than the `BlazorWasmAuth` app, uncomment the code that configures the cookie (ConfigureApplicationCookie) in the `Backend` app's `Program` file. The default values are:

- Same-site mode: SameSiteMode.Lax
- Secure policy: CookieSecurePolicy.SameAsRequest

Change the values to:

- Same-site mode: SameSiteMode.None
- Secure policy: CookieSecurePolicy.Always

diff

```
- options.Cookie.SameSite = SameSiteMode.Lax;
- options.Cookie.SecurePolicy = CookieSecurePolicy.SameAsRequest;
+ options.Cookie.SameSite = SameSiteMode.None;
+ options.Cookie.SecurePolicy = CookieSecurePolicy.Always;
```

For more information on same-site cookie settings, see the following resources:

- Set-Cookie: SameSite=<samesite-value> (MDN documentation)
- Cookies: HTTP State Management Mechanism (RFC Draft 6265, Section 4.1)

Antiforgery support

Only the logout endpoint (`/logout`) in the `Backend` app requires attention to mitigate the threat of Cross-Site Request Forgery (CSRF).

The logout endpoint checks for an empty body to prevent CSRF attacks. By requiring a body, the request must be made from JavaScript, which is the only way to access the authentication cookie. The logout endpoint can't be accessed by a form-based POST. This prevents a malicious site from logging the user out.

Furthermore, the endpoint is protected by authorization (RequireAuthorization) to prevent anonymous access.

The `BlazorWasmAuth` client app is simply required to pass an empty object `{}` in the body of the request.

Outside of the logout endpoint, antiforgery mitigation is only required when submitting form data to the server encoded as `application/x-www-form-urlencoded`, `multipart/form-data`, or `text/plain`. Blazor manages CSRF mitigation for forms in most cases. For more information, see ASP.NET Core Blazor authentication and authorization and ASP.NET Core Blazor forms overview.

Requests to other server API endpoints (web API) with `application/json`-encoded content and CORS enabled doesn't require CSRF protection. This is why no CSRF protection is required for the `Backend` app's data processing (`/data-processing`) endpoint. The roles (`/roles`) endpoint doesn't need CSRF protection because it's a GET endpoint that doesn't modify any state.

Troubleshoot

Logging

To enable debug or trace logging for Blazor WebAssembly authentication, see ASP.NET Core Blazor logging.

Common errors

Check each project's configuration. Confirm that the URLs are correct:

- `Backend` project
  - `appsettings.json`
    - `BackendUrl`
    - `FrontendUrl`
  - `Backend.http`: `Backend_HostAddress`
- `BlazorWasmAuth` project: `wwwroot/appsettings.json`
  - `BackendUrl`
  - `FrontendUrl`

If the configuration appears correct:

- Analyze application logs.
- Examine the network traffic between the `BlazorWasmAuth` app and `Backend` app with the browser's developer tools. Often, an exact error message or a message with a clue to what's causing the problem is returned to the client by the backend app after making a request. Developer tools guidance is found in the following articles:
- Google Chrome (Google documentation)
- Microsoft Edge
- Mozilla Firefox (Mozilla documentation)

The documentation team responds to document feedback and bugs in articles. Open an issue using the **Open a documentation issue** link at the bottom of the article. The team isn't able to provide product support. Several public support forums are available to assist with troubleshooting an app. We recommend the following:

- Stack Overflow (tag: blazor)
- ASP.NET Core Slack Team
- Blazor Gitter

The preceding forums are not owned or controlled by Microsoft.

For non-security, non-sensitive, and non-confidential reproducible framework bug reports, open an issue with the ASP.NET Core product unit. Don't open an issue with the product unit until you've thoroughly investigated the cause of a problem and can't resolve it on your own and with the help of the community on a public support forum. The product unit isn't able to troubleshoot individual apps that are broken due to simple misconfiguration or use cases involving third-party services. If a report is sensitive or confidential in nature or describes a potential security flaw in the product that cyberattackers may exploit, see Reporting security issues and bugs (dotnet/aspnetcore GitHub repository).

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes, or app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE for any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in InPrivate or Incognito mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`

- In the **Arguments** field, provide the command-line option that the browser uses to open in InPrivate or Incognito mode. Some browsers require the URL of the app.
  - Microsoft Edge: Use `-inprivate`.
  - Google Chrome: Use `--incognito --new-window {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
  - Mozilla Firefox: Use `-private -url {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
- Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
- Select the **OK** button.
- To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
- Make sure that the browser is closed by the IDE for any change to the app, test user, or provider configuration.

App upgrades

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Clear the local system's NuGet package caches by executing dotnet nuget locals all --clear from a command shell.
2. Delete the project's `bin` and `obj` folders.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

> ⓘ **Note**
>
> Use of package versions incompatible with the app's target framework isn't supported. For information on a package, use the NuGet Gallery or FuGet Package Explorer.

Inspect the user's claims

To troubleshoot problems with user claims, the following `UserClaims` component can be used directly in apps or serve as the basis for further customization.

`UserClaims.razor`:

```razor
@page "/user-claims"
@using System.Security.Claims
@attribute [Authorize]

<PageTitle>User Claims</PageTitle>

<h1>User Claims</h1>

**Name**: @AuthenticatedUser?.Identity?.Name

<h2>Claims</h2>

@foreach (var claim in AuthenticatedUser?.Claims ?? Array.Empty<Claim>())
{
    <p class="claim">@(claim.Type): @claim.Value</p>
}

@code {
    [CascadingParameter]
    private Task<AuthenticationState>? AuthenticationState { get; set; }

    public ClaimsPrincipal? AuthenticatedUser { get; set; }

    protected override async Task OnInitializedAsync()
    {
        if (AuthenticationState is not null)
        {
            var state = await AuthenticationState;
            AuthenticatedUser = state.User;
        }
    }
}
```

Secure an ASP.NET Core Blazor WebAssembly standalone app with the Authentication library

Article • 09/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to secure an ASP.NET Core Blazor WebAssembly standalone app with the Blazor WebAssembly Authentication library.

The Blazor WebAssembly Authentication library (`Authentication.js`) only supports the Proof Key for Code Exchange (PKCE) authorization code flow via the Microsoft Authentication Library (MSAL, msal.js). To implement other grant flows, access the MSAL guidance to implement MSAL directly, but we don't support or recommend the use of grant flows other than PKCE for Blazor apps.

For Microsoft Entra (ME-ID) and Azure Active Directory B2C (AAD B2C) guidance, don't follow the guidance in this topic. See Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID or Secure an ASP.NET Core Blazor WebAssembly standalone app with Azure Active Directory B2C.

For additional security scenario coverage after reading this article, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Walkthrough

The subsections of the walkthrough explain how to:

- Register an app
- Create the Blazor app
- Run the app

Register an app

Register an app with an OpenID Connect (OIDC) Identity Provider (IP) following the guidance provided by the maintainer of the IP.

Record the following information:

- Authority (for example, `https://accounts.google.com/`).
- Application (client) ID (for example, `2...7-e...q.apps.googleusercontent.com`).
- Additional IP configuration (see the IP's documentation).

> **Note**
>
> The IP must use OIDC. For example, Facebook's IP isn't an OIDC-compliant provider, so the guidance in this topic doesn't work with the Facebook IP. For more information, see Secure ASP.NET Core Blazor WebAssembly.

Create the Blazor app

To create a standalone Blazor WebAssembly app that uses the Microsoft.AspNetCore.Components.WebAssembly.Authentication library, follow the guidance for your choice of tooling. If adding support for authentication, see the Parts of the app section of this article for guidance on setting up and configuring the app.

Visual Studio

To create a new Blazor WebAssembly project with an authentication mechanism:

After choosing the **Blazor WebAssembly App** template, set the **Authentication type** to **Individual Accounts**.

The **Individual Accounts** selection uses ASP.NET Core's Identity system. This selection adds authentication support and doesn't result in storing users in a database. The following sections of this article provide further details.

Configure the app

Configure the app following the IP's guidance. At a minimum, the app requires the `Local:Authority` and `Local:ClientId` configuration settings in the app's `wwwroot/appsettings.json` file:

JSON

```
{
  "Local": {
    "Authority": "{AUTHORITY}",
    "ClientId": "{CLIENT ID}"
  }
}
```

Google OAuth 2.0 OIDC example for an app that runs on the `localhost` address at port 5001:

JSON

```
{
  "Local": {
    "Authority": "https://accounts.google.com/",
    "ClientId": "2...7-e...q.apps.googleusercontent.com",
    "PostLogoutRedirectUri": "https://localhost:5001/authentication/logout-
callback",
    "RedirectUri": "https://localhost:5001/authentication/login-callback",
    "ResponseType": "code"
  }
}
```

The redirect URI (`https://localhost:5001/authentication/login-callback`) is registered in the Google APIs console in **Credentials** > `{NAME}` > **Authorized redirect URIs**, where `{NAME}` is the app's client name in the **OAuth 2.0 Client IDs** app list of the Google APIs console.

> **Note**
>
> Supplying the port number for a `localhost` redirect URI isn't required for some OIDC IPs per the OAuth 2.0 specification. Some IPs permit the redirect URI for loopback addresses to omit the port. Others allow the use of a wildcard for the port number (for example, `*`). For additional information, see the IP's documentation.

Run the app

Use one of the following approaches to run the app:

- Visual Studio
  - Select the **Run** button.
  - Use **Debug** > **Start Debugging** from the menu.
  - Press F5.

- .NET CLI command shell: Execute the `dotnet watch` (or `dotnet run`) command from the app's folder.

Parts of the app

This section describes the parts of an app generated from the Blazor WebAssembly project template and how the app is configured. There's no specific guidance to follow in this section for a basic working application if you created the app using the guidance in the Walkthrough section. The guidance in this section is helpful for updating an app to authenticate and authorize users. However, an alternative approach to updating an app is to create a new app from the guidance in the Walkthrough section and moving the app's components, classes, and resources to the new app.

Authentication package

When an app is created to use Individual User Accounts, the app automatically receives a package reference for the Microsoft.AspNetCore.Components.WebAssembly.Authentication package. The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the Microsoft.AspNetCore.Components.WebAssembly.Authentication package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Authentication service support

Support for authenticating users using OpenID Connect (OIDC) is registered in the service container with the AddOidcAuthentication extension method provided by the Microsoft.AspNetCore.Components.WebAssembly.Authentication package.

The AddOidcAuthentication method accepts a callback to configure the parameters required to authenticate an app using OIDC. The values required for configuring the app can be obtained from the OIDC-compliant IP. Obtain the values when you register the app, which typically occurs in their online portal.

For a new app, provide values for the `{AUTHORITY}` and `{CLIENT ID}` placeholders in the following configuration. Provide other configuration values that are required for use with the app's IP. The example is for Google, which requires `PostLogoutRedirectUri`, `RedirectUri`, and `ResponseType`. If adding authentication to an app, manually add the following code and configuration to the app with values for the placeholders and other configuration values.

In the `Program` file:

C#

```
builder.Services.AddOidcAuthentication(options =>
{
    builder.Configuration.Bind("Local", options.ProviderOptions);
});
```

`wwwroot/appsettings.json` configuration

Configuration is supplied by the `wwwroot/appsettings.json` file:

JSON

```
{
  "Local": {
    "Authority": "{AUTHORITY}",
    "ClientId": "{CLIENT ID}"
  }
}
```

Access token scopes

The Blazor WebAssembly template automatically configures default scopes for `openid` and `profile`.

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default token scopes of the OidcProviderOptions. If adding authentication to an app, manually add the following code and configure the scope URI.

In the `Program` file:

C#

```
builder.Services.AddOidcAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultScopes.Add("{SCOPE URI}");
});
```

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

razor

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.Web.Virtualization
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

HTML

```
<script
src="_content/Microsoft.AspNetCore.Components.WebAssembly.Authentication/Aut
henticationService.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `App` component (`App.razor`) isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to use. Inspect the `App` component (`App.razor`) in the generated app.

- Inspect the `App` component (`App.razor`) in reference source. Select the version from the branch selector, and search for the component in the `ProjectTemplates` folder of the repository because it has moved over the years.

  > **Note**
  >
  > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

RedirectToLogin component

The `RedirectToLogin` component (`RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- The current URL that the user is attempting to access is maintained by so that they can be returned to that page if authentication is successful using:
  - Navigation history state in ASP.NET Core in .NET 7 or later.
  - A query string in ASP.NET Core in .NET 6 or earlier.

Inspect the `RedirectToLogin` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

LoginDisplay component

The `LoginDisplay` component (`LoginDisplay.razor`) is rendered in the `MainLayout` component (`MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current user name.
  - Offers a link to the user profile page in ASP.NET Core Identity.
  - Offers a button to log out of the app.
- For anonymous users:
  - Offers the option to register.
  - Offers the option to log in.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `LoginDisplay` component isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to use. Inspect the `LoginDisplay` component in the generated app.

- Inspect the `LoginDisplay` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component. The templated content for `Hosted` equal to `true` is used.

  > **Note**
  >
  > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the Microsoft.AspNetCore.Components.WebAssembly.Authentication package.
- Manages performing the appropriate actions at each stage of authentication.

razor

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string? Action { get; set; }
}
```

> **Note**
>
> Nullable reference types (NRTs) and .NET compiler null-state static analysis is supported in ASP.NET Core in .NET 6 or later. Prior to the release of ASP.NET Core in .NET 6, the `string` type appears without the null type designation (`?`).

Troubleshoot

Logging

To enable debug or trace logging for Blazor WebAssembly authentication, see the *Client-side authentication logging* section of ASP.NET Core Blazor logging with the article version selector set to ASP.NET Core 7.0 or later.

Common errors

- Misconfiguration of the app or Identity Provider (IP)

The most common errors are caused by incorrect configuration. The following are a few examples:

- Depending on the requirements of the scenario, a missing or incorrect Authority, Instance, Tenant ID, Tenant domain, Client ID, or Redirect URI prevents an app from authenticating clients.
- Incorrect request scopes prevent clients from accessing server web API endpoints.
- Incorrect or missing server API permissions prevent clients from accessing server web API endpoints.
- Running the app at a different port than is configured in the Redirect URI of the IP's app registration. Note that a port isn't required for Microsoft Entra ID and an app running at a `localhost` development testing address, but the app's port configuration and the port where the app is running must match for non-`localhost` addresses.

Configuration sections of this article's guidance show examples of the correct configuration. Carefully check each section of the article looking for app and IP misconfiguration.

If the configuration appears correct:

- Analyze application logs.
- Examine the network traffic between the client app and the IP or server app with the browser's developer tools. Often, an exact error message or a message with a clue to what's causing the problem is returned to the client by the IP or server app after making a request. Developer tools guidance is found in the following articles:
  - Google Chrome (Google documentation)
  - Microsoft Edge
  - Mozilla Firefox (Mozilla documentation)
- For releases of Blazor where a JSON Web Token (JWT) is used, decode the contents of the token used for authenticating a client or accessing a server web API, depending on where the problem is occurring. For more information, see Inspect the content of a JSON Web Token (JWT).

The documentation team responds to document feedback and bugs in articles (open an issue from the **This page** feedback section) but is unable to provide product support. Several public support forums are available to assist with troubleshooting an app. We recommend the following:

- Stack Overflow (tag: blazor)
- ASP.NET Core Slack Team

    - Blazor Gitter

    The preceding forums are not owned or controlled by Microsoft.

    For non-security, non-sensitive, and non-confidential reproducible framework bug reports, open an issue with the ASP.NET Core product unit. Don't open an issue with the product unit until you've thoroughly investigated the cause of a problem and can't resolve it on your own and with the help of the community on a public support forum. The product unit isn't able to troubleshoot individual apps that are broken due to simple misconfiguration or use cases involving third-party services. If a report is sensitive or confidential in nature or describes a potential security flaw in the product that cyberattackers may exploit, see Reporting security issues and bugs (dotnet/aspnetcore GitHub repository).

- Unauthorized client for ME-ID

    > info: Microsoft.AspNetCore.Authorization.DefaultAuthorizationService[2]
    > Authorization failed. These requirements were not met:
    > DenyAnonymousAuthorizationRequirement: Requires an authenticated user.

    Login callback error from ME-ID:
    - Error: `unauthorized_client`
    - Description: `AADB2C90058: The provided application is not configured to allow public clients.`

    To resolve the error:

    1. In the Azure portal, access the app's manifest.
    2. Set the allowPublicClient attribute to `null` or `true`.

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE for any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in InPrivate or Incognito mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in InPrivate or Incognito mode. Some browsers require the URL of the app.
    - Microsoft Edge: Use `-inprivate`.
    - Google Chrome: Use `--incognito --new-window {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
    - Mozilla Firefox: Use `-private -url {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.
  - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
  - Make sure that the browser is closed by the IDE for any change to the app, test user, or provider configuration.

App upgrades

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Clear the local system's NuGet package caches by executing dotnet nuget locals all --clear from a command shell.
2. Delete the project's `bin` and `obj` folders.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

> **Note**
>
> Use of package versions incompatible with the app's target framework isn't supported. For information on a package, use the NuGet Gallery or FuGet Package Explorer.

Inspect the user

The following `User` component can be used directly in apps or serve as the basis for further customization.

`User.razor`:

razor

```
@page "/user"
@attribute [Authorize]
@using System.Text.Json
@using System.Security.Claims
@inject IAccessTokenProvider AuthorizationService

<h1>@AuthenticatedUser?.Identity?.Name</h1>

<h2>Claims</h2>

@foreach (var claim in AuthenticatedUser?.Claims ?? Array.Empty<Claim>())
{
    <p class="claim">@(claim.Type): @claim.Value</p>
}

<h2>Access token</h2>

<p id="access-token">@AccessToken?.Value</p>

<h2>Access token claims</h2>

@foreach (var claim in GetAccessTokenClaims())
{
    <p>@(claim.Key): @claim.Value.ToString()</p>
}
```

```
@if (AccessToken != null)
{
    <h2>Access token expires</h2>

    <p>Current time: <span id="current-time">@DateTimeOffset.Now</span></p>
    <p id="access-token-expires">@AccessToken.Expires</p>

    <h2>Access token granted scopes (as reported by the API)</h2>

    @foreach (var scope in AccessToken.GrantedScopes)
    {
        <p>Scope: @scope</p>
    }
}

@code {
    [CascadingParameter]
    private Task<AuthenticationState> AuthenticationState { get; set; }

    public ClaimsPrincipal AuthenticatedUser { get; set; }
    public AccessToken AccessToken { get; set; }

    protected override async Task OnInitializedAsync()
    {
        await base.OnInitializedAsync();
        var state = await AuthenticationState;
        var accessTokenResult = await
AuthorizationService.RequestAccessToken();

        if (!accessTokenResult.TryGetToken(out var token))
        {
            throw new InvalidOperationException(
                "Failed to provision the access token.");
        }

        AccessToken = token;

        AuthenticatedUser = state.User;
    }

    protected IDictionary<string, object> GetAccessTokenClaims()
    {
        if (AccessToken == null)
        {
            return new Dictionary<string, object>();
        }

        // header.payload.signature
        var payload = AccessToken.Value.Split(".")[1];
        var base64Payload = payload.Replace('-', '+').Replace('_', '/')
            .PadRight(payload.Length + (4 - payload.Length % 4) % 4, '=');

        return JsonSerializer.Deserialize<IDictionary<string, object>>(
            Convert.FromBase64String(base64Payload));
```

```
    }
}
```

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Example encoded JWT (shortened for display):

> eyJ0eXAiOiJKV1QiLCJhbGciOiJSUzI1NiIsImtpZCI6Ilg1ZVhrNHh5b2pORnVtMWtsMll0djhkbE5QNC1j ...
> bQdHBHGcQQRbW7Wmo6SWYG4V_bU55Ug_PW4pLPr20tTS8Ct7_uwy9DWrzCMzpD-EiwT5IjXwlGX3IXVjHIlX50IVIydBoPQtadvT7saKo1G5Jmutgq41o-dmz6-yBMKV2_nXA25Q

Example JWT decoded by the tool for an app that authenticates against Azure AAD B2C:

JSON

```
{
  "typ": "JWT",
  "alg": "RS256",
  "kid": "X5eXk4xyojNFum1kl2Ytv8dlNP4-c57dO6QGTVBwaNk"
}.{
  "exp": 1610059429,
  "nbf": 1610055829,
  "ver": "1.0",
  "iss": "https://mysiteb2c.b2clogin.com/11112222-bbbb-3333-cccc-4444dddd5555/v2.0/",
  "sub": "aaaaaaaa-0000-1111-2222-bbbbbbbbbbbb",
  "aud": "00001111-aaaa-2222-bbbb-3333cccc4444",
  "nonce": "bbbb0000-cccc-1111-dddd-2222eeee3333",
  "iat": 1610055829,
  "auth_time": 1610055822,
  "idp": "idp.com",
  "tfp": "B2C_1_signupsignin"
}.[Signature]
```

Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Accounts

Article • 10/20/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to create a standalone Blazor WebAssembly app that uses Microsoft Accounts with Microsoft Entra (ME-ID) for authentication.

For additional security scenario coverage after reading this article, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Walkthrough

The subsections of the walkthrough explain how to:

- Create a tenant in Azure
- Register an app in Azure
- Create the Blazor app
- Run the app

Create a tenant in Azure

Follow the guidance in Quickstart: Set up a tenant to create a tenant in ME-ID.

Register an app in Azure

Register an ME-ID app:

1. Navigate to **Microsoft Entra ID** in the Azure portal. Select **App registrations** in the sidebar. Select the **New registration** button.
2. Provide a **Name** for the app (for example, **Blazor Standalone ME-ID MS Accounts**).

3. In **Supported account types**, select **Accounts in any organizational directory (Any Microsoft Entra ID directory – Multitenant)**.
4. Set the **Redirect URI** dropdown list to **Single-page application (SPA)** and provide the following redirect URI: `https://localhost/authentication/login-callback`. If you know the production redirect URI for the Azure default host (for example, `azurewebsites.net`) or the custom domain host (for example, `contoso.com`), you can also add the production redirect URI at the same time that you're providing the `localhost` redirect URI. Be sure to include the port number for non-`:443` ports in any production redirect URIs that you add.
5. If you're using an unverified publisher domain, clear the **Permissions** > **Grant admin consent to openid and offline_access permissions** checkbox. If the publisher domain is verified, this checkbox isn't present.
6. Select **Register**.

> **Note**
>
> Supplying the port number for a `localhost` ME-ID redirect URI isn't required. For more information, see Redirect URI (reply URL) restrictions and limitations: Localhost exceptions (Entra documentation).

Record the Application (client) ID (for example, `00001111-aaaa-2222-bbbb-3333cccc4444`).

In **Authentication** > **Platform configurations** > **Single-page application**:

1. Confirm the redirect URI of `https://localhost/authentication/login-callback` is present.
2. In the **Implicit grant** section, ensure that the checkboxes for **Access tokens** and **ID tokens** aren't selected. **Implicit grant isn't recommended for Blazor apps using MSAL v2.0 or later.** For more information, see Secure ASP.NET Core Blazor WebAssembly.
3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button if you made changes.

Create the Blazor app

Create the app. Replace the placeholders in the following command with the information recorded earlier and execute the following command in a command shell:

.NET CLI

```
dotnet new blazorwasm -au SingleOrg --client-id "{CLIENT ID}" --tenant-id
"common" -o {PROJECT NAME}
```

Expand table

Placeholder	Azure portal name	Example
`{PROJECT NAME}`	—	`BlazorSample`
`{CLIENT ID}`	Application (client) ID	`00001111-aaaa-2222-bbbb-3333cccc4444`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the project's name.

Add a pair of MsalProviderOptions for `openid` and `offline_access` DefaultAccessTokenScopes:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("openid");
    options.ProviderOptions.DefaultAccessTokenScopes.Add("offline_access");
});
```

Run the app

Use one of the following approaches to run the app:

- Visual Studio
  - Select the **Run** button.
  - Use **Debug** > **Start Debugging** from the menu.
  - Press `F5`.
- .NET CLI command shell: Execute the `dotnet watch` (or `dotnet run`) command from the app's folder.

Parts of the app

This section describes the parts of an app generated from the Blazor WebAssembly project template and how the app is configured. There's no specific guidance to follow in this section for a basic working application if you created the app using the guidance

in the Walkthrough section. The guidance in this section is helpful for updating an app to authenticate and authorize users. However, an alternative approach to updating an app is to create a new app from the guidance in the Walkthrough section and moving the app's components, classes, and resources to the new app.

Authentication package

When an app is created to use Work or School Accounts (`SingleOrg`), the app automatically receives a package reference for the Microsoft Authentication Library (Microsoft.Authentication.WebAssembly.Msal). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the Microsoft.Authentication.WebAssembly.Msal package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

The Microsoft.Authentication.WebAssembly.Msal package transitively adds the Microsoft.AspNetCore.Components.WebAssembly.Authentication package to the app.

Authentication service support

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the Microsoft.Authentication.WebAssembly.Msal package. This method sets up all of the services required for the app to interact with the Identity Provider (IP).

In the `Program` file:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAd",
options.ProviderOptions.Authentication);
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the ME-ID configuration when you register the app.

`wwwroot/appsettings.json` configuration

Configuration is supplied by the `wwwroot/appsettings.json` file:

JSON

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/common",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": true
  }
}
```

Example:

JSON

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/common",
    "ClientId": "00001111-aaaa-2222-bbbb-3333cccc4444",
    "ValidateAuthority": true
  }
}
```

Access token scopes

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default access token scopes of the MsalProviderOptions:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

Specify additional scopes with `AdditionalScopesToConsent`:

C#

```
options.ProviderOptions.AdditionalScopesToConsent.Add("{ADDITIONAL SCOPE
URI}");
```

> **Note**
>
> AdditionalScopesToConsent for Microsoft Graph via the Microsoft Entra ID consent UI when a user first uses an app registered in Microsoft Azure. For more information, see Use Graph API with ASP.NET Core Blazor WebAssembly.

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests
- Quickstart: Configure an application to expose web APIs

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case-sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

razor

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
```

```
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.Web.Virtualization
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

HTML

```
<script
src="_content/Microsoft.Authentication.WebAssembly.Msal/AuthenticationServic
e.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `App` component (`App.razor`) isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to use. Inspect the `App` component (`App.razor`) in the generated app.
- Inspect the `App` component (`App.razor`) in reference source. Select the version from the branch selector, and search for the component in the `ProjectTemplates`

folder of the repository because it has moved over the years.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

RedirectToLogin component

The `RedirectToLogin` component (`RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- The current URL that the user is attempting to access is maintained by so that they can be returned to that page if authentication is successful using:
  - Navigation history state in ASP.NET Core in .NET 7 or later.
  - A query string in ASP.NET Core in .NET 6 or earlier.

Inspect the `RedirectToLogin` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

LoginDisplay component

The `LoginDisplay` component (`LoginDisplay.razor`) is rendered in the `MainLayout` component (`MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current user name.
  - Offers a link to the user profile page in ASP.NET Core Identity.
  - Offers a button to log out of the app.

- For anonymous users:
  - Offers the option to register.
  - Offers the option to log in.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `LoginDisplay` component isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to use. Inspect the `LoginDisplay` component in the generated app.

- Inspect the `LoginDisplay` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component. The templated content for `Hosted` equal to `true` is used.

  > **Note**
  >
  > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the Microsoft.AspNetCore.Components.WebAssembly.Authentication package.
- Manages performing the appropriate actions at each stage of authentication.

razor

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
```

```
    public string? Action { get; set; }
}
```

> ⓘ Note
>
> Nullable reference types (NRTs) and .NET compiler null-state static analysis is supported in ASP.NET Core in .NET 6 or later. Prior to the release of ASP.NET Core in .NET 6, the `string` type appears without the null type designation (`?`).

Troubleshoot

Logging

To enable debug or trace logging for Blazor WebAssembly authentication, see the *Client-side authentication logging* section of ASP.NET Core Blazor logging with the article version selector set to ASP.NET Core 7.0 or later.

Common errors

- Misconfiguration of the app or Identity Provider (IP)

  The most common errors are caused by incorrect configuration. The following are a few examples:
  - Depending on the requirements of the scenario, a missing or incorrect Authority, Instance, Tenant ID, Tenant domain, Client ID, or Redirect URI prevents an app from authenticating clients.
  - Incorrect request scopes prevent clients from accessing server web API endpoints.
  - Incorrect or missing server API permissions prevent clients from accessing server web API endpoints.
  - Running the app at a different port than is configured in the Redirect URI of the IP's app registration. Note that a port isn't required for Microsoft Entra ID and an app running at a `localhost` development testing address, but the app's port configuration and the port where the app is running must match for non-`localhost` addresses.

  Configuration sections of this article's guidance show examples of the correct configuration. Carefully check each section of the article looking for app and IP misconfiguration.

If the configuration appears correct:

- Analyze application logs.
- Examine the network traffic between the client app and the IP or server app with the browser's developer tools. Often, an exact error message or a message with a clue to what's causing the problem is returned to the client by the IP or server app after making a request. Developer tools guidance is found in the following articles:
  - Google Chrome (Google documentation)
  - Microsoft Edge
  - Mozilla Firefox (Mozilla documentation)
- For releases of Blazor where a JSON Web Token (JWT) is used, decode the contents of the token used for authenticating a client or accessing a server web API, depending on where the problem is occurring. For more information, see Inspect the content of a JSON Web Token (JWT).

The documentation team responds to document feedback and bugs in articles (open an issue from the **This page** feedback section) but is unable to provide product support. Several public support forums are available to assist with troubleshooting an app. We recommend the following:

- Stack Overflow (tag: blazor)
- ASP.NET Core Slack Team
- Blazor Gitter

The preceding forums are not owned or controlled by Microsoft.

For non-security, non-sensitive, and non-confidential reproducible framework bug reports, open an issue with the ASP.NET Core product unit. Don't open an issue with the product unit until you've thoroughly investigated the cause of a problem and can't resolve it on your own and with the help of the community on a public support forum. The product unit isn't able to troubleshoot individual apps that are broken due to simple misconfiguration or use cases involving third-party services. If a report is sensitive or confidential in nature or describes a potential security flaw in the product that cyberattackers may exploit, see Reporting security issues and bugs (dotnet/aspnetcore GitHub repository).

- Unauthorized client for ME-ID

> info: Microsoft.AspNetCore.Authorization.DefaultAuthorizationService[2]
> Authorization failed. These requirements were not met:
> DenyAnonymousAuthorizationRequirement: Requires an authenticated user.

Login callback error from ME-ID:

- Error: `unauthorized_client`
- Description: `AADB2C90058: The provided application is not configured to allow public clients.`

To resolve the error:

1. In the Azure portal, access the app's manifest.
2. Set the allowPublicClient attribute to `null` or `true`.

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE for any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in InPrivate or Incognito mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`

- In the **Arguments** field, provide the command-line option that the browser uses to open in InPrivate or Incognito mode. Some browsers require the URL of the app.
  - Microsoft Edge: Use `-inprivate`.
  - Google Chrome: Use `--incognito --new-window {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
  - Mozilla Firefox: Use `-private -url {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
- Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
- Select the **OK** button.
- To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
- Make sure that the browser is closed by the IDE for any change to the app, test user, or provider configuration.

App upgrades

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Clear the local system's NuGet package caches by executing dotnet nuget locals all --clear from a command shell.
2. Delete the project's `bin` and `obj` folders.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

> ⓘ **Note**
>
> Use of package versions incompatible with the app's target framework isn't supported. For information on a package, use the NuGet Gallery or FuGet Package Explorer.

Inspect the user

The following `User` component can be used directly in apps or serve as the basis for further customization.

`User.razor`:

razor

```razor
@page "/user"
@attribute [Authorize]
@using System.Text.Json
@using System.Security.Claims
@inject IAccessTokenProvider AuthorizationService

<h1>@AuthenticatedUser?.Identity?.Name</h1>

<h2>Claims</h2>

@foreach (var claim in AuthenticatedUser?.Claims ?? Array.Empty<Claim>())
{
    <p class="claim">@(claim.Type): @claim.Value</p>
}

<h2>Access token</h2>

<p id="access-token">@AccessToken?.Value</p>

<h2>Access token claims</h2>

@foreach (var claim in GetAccessTokenClaims())
{
    <p>@(claim.Key): @claim.Value.ToString()</p>
}

@if (AccessToken != null)
{
    <h2>Access token expires</h2>

    <p>Current time: <span id="current-time">@DateTimeOffset.Now</span></p>
    <p id="access-token-expires">@AccessToken.Expires</p>

    <h2>Access token granted scopes (as reported by the API)</h2>

    @foreach (var scope in AccessToken.GrantedScopes)
    {
        <p>Scope: @scope</p>
    }
}

@code {
    [CascadingParameter]
    private Task<AuthenticationState> AuthenticationState { get; set; }

    public ClaimsPrincipal AuthenticatedUser { get; set; }
    public AccessToken AccessToken { get; set; }

    protected override async Task OnInitializedAsync()
    {
```

```
        await base.OnInitializedAsync();
        var state = await AuthenticationState;
        var accessTokenResult = await
AuthorizationService.RequestAccessToken();

        if (!accessTokenResult.TryGetToken(out var token))
        {
            throw new InvalidOperationException(
                "Failed to provision the access token.");
        }

        AccessToken = token;

        AuthenticatedUser = state.User;
    }

    protected IDictionary<string, object> GetAccessTokenClaims()
    {
        if (AccessToken == null)
        {
            return new Dictionary<string, object>();
        }

        // header.payload.signature
        var payload = AccessToken.Value.Split(".")[1];
        var base64Payload = payload.Replace('-', '+').Replace('_', '/')
            .PadRight(payload.Length + (4 - payload.Length % 4) % 4, '=');

        return JsonSerializer.Deserialize<IDictionary<string, object>>(
            Convert.FromBase64String(base64Payload));
    }
}
```

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Example encoded JWT (shortened for display):

> eyJ0eXAiOiJKV1QiLCJhbGciOiJSUzI1NiIsImtpZCI6Ilg1ZVhrNHh5b2pORnVtMWtsMll0djhkbE5QNC1j ...
> bQdHBHGcQQRbW7Wmo6SWYG4V_bU55Ug_PW4pLPr20tTS8Ct7_uwy9DWrzCMzpD-EiwT5IjXwlGX3IXVjHIlX50IVIydBoPQtadvT7saKo1G5Jmutgq41o-dmz6-yBMKV2_nXA25Q

Example JWT decoded by the tool for an app that authenticates against Azure AAD B2C:

```
JSON
```

```
{
  "typ": "JWT",
  "alg": "RS256",
  "kid": "X5eXk4xyojNFum1kl2Ytv8dlNP4-c57dO6QGTVBwaNk"
}.{
  "exp": 1610059429,
  "nbf": 1610055829,
  "ver": "1.0",
  "iss": "https://mysiteb2c.b2clogin.com/11112222-bbbb-3333-cccc-
4444dddd5555/v2.0/",
  "sub": "aaaaaaaa-0000-1111-2222-bbbbbbbbbbbb",
  "aud": "00001111-aaaa-2222-bbbb-3333cccc4444",
  "nonce": "bbbb0000-cccc-1111-dddd-2222eeee3333",
  "iat": 1610055829,
  "auth_time": 1610055822,
  "idp": "idp.com",
  "tfp": "B2C_1_signupsignin"
}.[Signature]
```

Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID

Article • 10/20/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to create a standalone Blazor WebAssembly app that uses Microsoft Entra ID (ME-ID) for authentication.

For additional security scenario coverage after reading this article, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Walkthrough

The subsections of the walkthrough explain how to:

- Create a tenant in Azure
- Register an app in Azure
- Create the Blazor app
- Run the app

Create a tenant in Azure

Follow the guidance in Quickstart: Set up a tenant to create a tenant in ME-ID.

Register an app in Azure

Register an ME-ID app:

1. Navigate to **Microsoft Entra ID** in the Azure portal. Select **Applications** > **App registrations** in the sidebar. Select the **New registration** button.
2. Provide a **Name** for the app (for example, **Blazor Standalone ME-ID**).

3. Choose a **Supported account types**. You may select **Accounts in this organizational directory only** for this experience.
4. Set the **Redirect URI** dropdown list to **Single-page application (SPA)** and provide the following redirect URI: `https://localhost/authentication/login-callback`. If you know the production redirect URI for the Azure default host (for example, `azurewebsites.net`) or the custom domain host (for example, `contoso.com`), you can also add the production redirect URI at the same time that you're providing the `localhost` redirect URI. Be sure to include the port number for non-`:443` ports in any production redirect URIs that you add.
5. If you're using an unverified publisher domain, clear the **Permissions** > **Grant admin consent to openid and offline_access permissions** checkbox. If the publisher domain is verified, this checkbox isn't present.
6. Select **Register**.

> ⓘ **Note**
>
> Supplying the port number for a `localhost` ME-ID redirect URI isn't required. For more information, see Redirect URI (reply URL) restrictions and limitations: Localhost exceptions (Entra documentation).

Record the following information:

- Application (client) ID (for example, `00001111-aaaa-2222-bbbb-3333cccc4444`)
- Directory (tenant) ID (for example, `aaaabbbb-0000-cccc-1111-dddd2222eeee`)

In **Authentication** > **Platform configurations** > **Single-page application**:

1. Confirm the redirect URI of `https://localhost/authentication/login-callback` is present.
2. In the **Implicit grant** section, ensure that the checkboxes for **Access tokens** and **ID tokens** aren't selected. **Implicit grant isn't recommended for Blazor apps using MSAL v2.0 or later.** For more information, see Secure ASP.NET Core Blazor WebAssembly.
3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button if you made changes.

Create the Blazor app

Create the app in an empty folder. Replace the placeholders in the following command with the information recorded earlier and execute the command in a command shell:

```
```

.NET CLI

```
dotnet new blazorwasm -au SingleOrg --client-id "{CLIENT ID}" -o {PROJECT
NAME} --tenant-id "{TENANT ID}"
```

Expand table

Placeholder	Azure portal name	Example
`{PROJECT NAME}`	—	`BlazorSample`
`{CLIENT ID}`	Application (client) ID	`00001111-aaaa-2222-bbbb-3333cccc4444`
`{TENANT ID}`	Directory (tenant) ID	`aaaabbbb-0000-cccc-1111-dddd2222eeee`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the project's name.

Add a MsalProviderOptions for `User.Read` permission with DefaultAccessTokenScopes:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes
        .Add("https://graph.microsoft.com/User.Read");
});
```

Run the app

Use one of the following approaches to run the app:

- Visual Studio
  - Select the **Run** button.
  - Use **Debug** > **Start Debugging** from the menu.
  - Press `F5`.
- .NET CLI command shell: Execute the `dotnet watch` (or `dotnet run`) command from the app's folder.

Parts of the app

This section describes the parts of an app generated from the Blazor WebAssembly project template and how the app is configured. There's no specific guidance to follow

in this section for a basic working application if you created the app using the guidance in the Walkthrough section. The guidance in this section is helpful for updating an app to authenticate and authorize users. However, an alternative approach to updating an app is to create a new app from the guidance in the Walkthrough section and moving the app's components, classes, and resources to the new app.

Authentication package

When an app is created to use Work or School Accounts (`SingleOrg`), the app automatically receives a package reference for the Microsoft Authentication Library (Microsoft.Authentication.WebAssembly.Msal). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the Microsoft.Authentication.WebAssembly.Msal package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

The Microsoft.Authentication.WebAssembly.Msal package transitively adds the Microsoft.AspNetCore.Components.WebAssembly.Authentication package to the app.

Authentication service support

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the Microsoft.Authentication.WebAssembly.Msal package. This method sets up the services required for the app to interact with the Identity Provider (IP).

In the `Program` file:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAd",
options.ProviderOptions.Authentication);
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the ME-ID configuration when you register the app.

`wwwroot/appsettings.json` configuration

Configuration is supplied by the `wwwroot/appsettings.json` file:

JSON

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/{TENANT ID}",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": true
  }
}
```

Example:

JSON

```
{
  "AzureAd": {
    "Authority":
"https://login.microsoftonline.com/e86c78e2-...-918e0565a45e",
    "ClientId": "00001111-aaaa-2222-bbbb-3333cccc4444",
    "ValidateAuthority": true
  }
}
```

Access token scopes

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default access token scopes of the MsalProviderOptions:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

Specify additional scopes with `AdditionalScopesToConsent`:

```
C#

options.ProviderOptions.AdditionalScopesToConsent.Add("{ADDITIONAL SCOPE
URI}");
```

> ⓘ Note
>
> AdditionalScopesToConsent isn't able to provision delegated user permissions for Microsoft Graph via the Microsoft Entra ID consent UI when a user first uses an app registered in Microsoft Azure. For more information, see Use Graph API with ASP.NET Core Blazor WebAssembly.

For more information, see the following resources:

- Request additional access tokens
- Attach tokens to outgoing requests
- Quickstart: Configure an application to expose web APIs
- Access token scopes for Microsoft Graph API

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

```
C#

builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case-sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

razor

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.Web.Virtualization
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

HTML

```
<script
src="_content/Microsoft.Authentication.WebAssembly.Msal/AuthenticationServic
e.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `App` component (`App.razor`) isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to

use. Inspect the `App` component (`App.razor`) in the generated app.

- Inspect the `App` component (`App.razor`) in reference source. Select the version from the branch selector, and search for the component in the `ProjectTemplates` folder of the repository because it has moved over the years.

  > **Note**
  >
  > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

RedirectToLogin component

The `RedirectToLogin` component (`RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- The current URL that the user is attempting to access is maintained by so that they can be returned to that page if authentication is successful using:
  - Navigation history state in ASP.NET Core in .NET 7 or later.
  - A query string in ASP.NET Core in .NET 6 or earlier.

Inspect the `RedirectToLogin` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

LoginDisplay component

The `LoginDisplay` component (`LoginDisplay.razor`) is rendered in the `MainLayout` component (`MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current user name.
  - Offers a link to the user profile page in ASP.NET Core Identity.
  - Offers a button to log out of the app.
- For anonymous users:
  - Offers the option to register.
  - Offers the option to log in.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `LoginDisplay` component isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to use. Inspect the `LoginDisplay` component in the generated app.

- Inspect the `LoginDisplay` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component. The templated content for `Hosted` equal to `true` is used.

  > **Note**
  >
  > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the Microsoft.AspNetCore.Components.WebAssembly.Authentication package.
- Manages performing the appropriate actions at each stage of authentication.

```
razor
```

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string? Action { get; set; }
}
```

> ⓘ Note
>
> Nullable reference types (NRTs) and .NET compiler null-state static analysis is supported in ASP.NET Core in .NET 6 or later. Prior to the release of ASP.NET Core in .NET 6, the `string` type appears without the null type designation (`?`).

Troubleshoot

Logging

To enable debug or trace logging for Blazor WebAssembly authentication, see the *Client-side authentication logging* section of ASP.NET Core Blazor logging with the article version selector set to ASP.NET Core 7.0 or later.

Common errors

- Misconfiguration of the app or Identity Provider (IP)

  The most common errors are caused by incorrect configuration. The following are a few examples:
  - Depending on the requirements of the scenario, a missing or incorrect Authority, Instance, Tenant ID, Tenant domain, Client ID, or Redirect URI prevents an app from authenticating clients.
  - Incorrect request scopes prevent clients from accessing server web API endpoints.
  - Incorrect or missing server API permissions prevent clients from accessing server web API endpoints.
  - Running the app at a different port than is configured in the Redirect URI of the IP's app registration. Note that a port isn't required for Microsoft Entra ID and an app running at a `localhost` development testing address, but the app's port

configuration and the port where the app is running must match for non-`localhost` addresses.

Configuration sections of this article's guidance show examples of the correct configuration. Carefully check each section of the article looking for app and IP misconfiguration.

If the configuration appears correct:

- Analyze application logs.
- Examine the network traffic between the client app and the IP or server app with the browser's developer tools. Often, an exact error message or a message with a clue to what's causing the problem is returned to the client by the IP or server app after making a request. Developer tools guidance is found in the following articles:
  - Google Chrome (Google documentation)
  - Microsoft Edge
  - Mozilla Firefox (Mozilla documentation)
- For releases of Blazor where a JSON Web Token (JWT) is used, decode the contents of the token used for authenticating a client or accessing a server web API, depending on where the problem is occurring. For more information, see Inspect the content of a JSON Web Token (JWT).

The documentation team responds to document feedback and bugs in articles (open an issue from the **This page** feedback section) but is unable to provide product support. Several public support forums are available to assist with troubleshooting an app. We recommend the following:

- Stack Overflow (tag: blazor)
- ASP.NET Core Slack Team
- Blazor Gitter

The preceding forums are not owned or controlled by Microsoft.

For non-security, non-sensitive, and non-confidential reproducible framework bug reports, open an issue with the ASP.NET Core product unit. Don't open an issue with the product unit until you've thoroughly investigated the cause of a problem and can't resolve it on your own and with the help of the community on a public support forum. The product unit isn't able to troubleshoot individual apps that are broken due to simple misconfiguration or use cases involving third-party services. If a report is sensitive or confidential in nature or describes a potential security flaw

in the product that cyberattackers may exploit, see Reporting security issues and bugs (dotnet/aspnetcore GitHub repository).

- Unauthorized client for ME-ID

  > info: Microsoft.AspNetCore.Authorization.DefaultAuthorizationService[2]
  > Authorization failed. These requirements were not met:
  > DenyAnonymousAuthorizationRequirement: Requires an authenticated user.

  Login callback error from ME-ID:
  - Error: `unauthorized_client`
  - Description: `AADB2C90058: The provided application is not configured to allow public clients.`

  To resolve the error:

  1. In the Azure portal, access the app's manifest.
  2. Set the allowPublicClient attribute to `null` or `true`.

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE for any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in InPrivate or Incognito mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.

- Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
  - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
  - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
  - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
- In the **Arguments** field, provide the command-line option that the browser uses to open in InPrivate or Incognito mode. Some browsers require the URL of the app.
  - Microsoft Edge: Use `-inprivate`.
  - Google Chrome: Use `--incognito --new-window {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
  - Mozilla Firefox: Use `-private -url {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
- Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
- Select the **OK** button.
- To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
- Make sure that the browser is closed by the IDE for any change to the app, test user, or provider configuration.

App upgrades

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Clear the local system's NuGet package caches by executing dotnet nuget locals all --clear from a command shell.
2. Delete the project's `bin` and `obj` folders.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

> **Note**

Use of package versions incompatible with the app's target framework isn't supported. For information on a package, use the NuGet Gallery or FuGet Package Explorer.

Inspect the user

The following `User` component can be used directly in apps or serve as the basis for further customization.

`User.razor`:

razor

```razor
@page "/user"
@attribute [Authorize]
@using System.Text.Json
@using System.Security.Claims
@inject IAccessTokenProvider AuthorizationService

<h1>@AuthenticatedUser?.Identity?.Name</h1>

<h2>Claims</h2>

@foreach (var claim in AuthenticatedUser?.Claims ?? Array.Empty<Claim>())
{
    <p class="claim">@(claim.Type): @claim.Value</p>
}

<h2>Access token</h2>

<p id="access-token">@AccessToken?.Value</p>

<h2>Access token claims</h2>

@foreach (var claim in GetAccessTokenClaims())
{
    <p>@(claim.Key): @claim.Value.ToString()</p>
}

@if (AccessToken != null)
{
    <h2>Access token expires</h2>

    <p>Current time: <span id="current-time">@DateTimeOffset.Now</span></p>
    <p id="access-token-expires">@AccessToken.Expires</p>

    <h2>Access token granted scopes (as reported by the API)</h2>

    @foreach (var scope in AccessToken.GrantedScopes)
    {
```

```
        <p>Scope: @scope</p>
    }
}

@code {
    [CascadingParameter]
    private Task<AuthenticationState> AuthenticationState { get; set; }

    public ClaimsPrincipal AuthenticatedUser { get; set; }
    public AccessToken AccessToken { get; set; }

    protected override async Task OnInitializedAsync()
    {
        await base.OnInitializedAsync();
        var state = await AuthenticationState;
        var accessTokenResult = await
AuthorizationService.RequestAccessToken();

        if (!accessTokenResult.TryGetToken(out var token))
        {
            throw new InvalidOperationException(
                "Failed to provision the access token.");
        }

        AccessToken = token;

        AuthenticatedUser = state.User;
    }

    protected IDictionary<string, object> GetAccessTokenClaims()
    {
        if (AccessToken == null)
        {
            return new Dictionary<string, object>();
        }

        // header.payload.signature
        var payload = AccessToken.Value.Split(".")[1];
        var base64Payload = payload.Replace('-', '+').Replace('_', '/')
            .PadRight(payload.Length + (4 - payload.Length % 4) % 4, '=');

        return JsonSerializer.Deserialize<IDictionary<string, object>>(
            Convert.FromBase64String(base64Payload));
    }
}
```

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Example encoded JWT (shortened for display):

> eyJ0eXAiOiJKV1QiLCJhbGciOiJSUzI1NiIsImtpZCI6Ilg1ZVhrNHh5b2pORnVtMWtsMll0djhkbE5QNC1j ...
> bQdHBHGcQQRbW7Wmo6SWYG4V_bU55Ug_PW4pLPr20tTS8Ct7_uwy9DWrzCMzpD-EiwT5IjXwlGX3IXVjHIlX50IVIydBoPQtadvT7saKo1G5Jmutgq41o-dmz6-yBMKV2_nXA25Q

Example JWT decoded by the tool for an app that authenticates against Azure AAD B2C:

JSON

```
{
  "typ": "JWT",
  "alg": "RS256",
  "kid": "X5eXk4xyojNFum1kl2Ytv8dlNP4-c57dO6QGTVBwaNk"
}.{
  "exp": 1610059429,
  "nbf": 1610055829,
  "ver": "1.0",
  "iss": "https://mysiteb2c.b2clogin.com/11112222-bbbb-3333-cccc-4444dddd5555/v2.0/",
  "sub": "aaaaaaaa-0000-1111-2222-bbbbbbbbbbbb",
  "aud": "00001111-aaaa-2222-bbbb-3333cccc4444",
  "nonce": "bbbb0000-cccc-1111-dddd-2222eeee3333",
  "iat": 1610055829,
  "auth_time": 1610055822,
  "idp": "idp.com",
  "tfp": "B2C_1_signupsignin"
}.[Signature]
```

Secure an ASP.NET Core Blazor WebAssembly standalone app with Azure Active Directory B2C

Article • 10/20/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to create a standalone Blazor WebAssembly app that uses Azure Active Directory (AAD) B2C for authentication.

For additional security scenario coverage after reading this article, see ASP.NET Core Blazor WebAssembly additional security scenarios.

Walkthrough

The subsections of the walkthrough explain how to:

- Create a tenant in Azure
- Register an app in Azure
- Create the Blazor app
- Run the app

Create a tenant in Azure

Follow the guidance in Tutorial: Create an Azure Active Directory B2C tenant to create an AAD B2C tenant.

Before proceeding with this article's guidance, confirm that you've selected the correct directory for the AAD B2C tenant.

Register an app in Azure

Register an AAD B2C app:

1. Navigate to **Azure AD B2C** in the Azure portal. Select **App registrations** in the sidebar. Select the **New registration** button.
2. Provide a **Name** for the app (for example, **Blazor Standalone AAD B2C**).
3. For **Supported account types**, select the multi-tenant option: **Accounts in any organizational directory or any identity provider. For authenticating users with Azure AD B2C.**
4. Set the **Redirect URI** dropdown list to **Single-page application (SPA)** and provide the following redirect URI: `https://localhost/authentication/login-callback`. If you know the production redirect URI for the Azure default host (for example, `azurewebsites.net`) or the custom domain host (for example, `contoso.com`), you can also add the production redirect URI at the same time that you're providing the `localhost` redirect URI. Be sure to include the port number for non-`:443` ports in any production redirect URIs that you add.
5. If you're using an unverified publisher domain, confirm that **Permissions** > **Grant admin consent to openid and offline_access permissions** is selected. If the publisher domain is verified, this checkbox isn't present.
6. Select **Register**.

> ⓘ **Note**
>
> Supplying the port number for a `localhost` AAD B2C redirect URI isn't required. For more information, see Redirect URI (reply URL) restrictions and limitations: Localhost exceptions (Entra documentation).

Record the following information:

- Application (client) ID (for example, `00001111-aaaa-2222-bbbb-3333cccc4444`).
- AAD B2C instance (for example, `https://contoso.b2clogin.com/`, which includes the trailing slash): The instance is the scheme and host of an Azure B2C app registration, which can be found by opening the **Endpoints** window from the **App registrations** page in the Azure portal.
- AAD B2C Primary/Publisher/Tenant domain (for example, `contoso.onmicrosoft.com`): The domain is available as the **Publisher domain** in the **Branding** blade of the Azure portal for the registered app.

In **Authentication** > **Platform configurations** > **Single-page application**:

1. Confirm the redirect URI of `https://localhost/authentication/login-callback` is present.
2. In the **Implicit grant** section, ensure that the checkboxes for **Access tokens** and **ID tokens** aren't selected. **Implicit grant isn't recommended for Blazor apps using**

MSAL v2.0 or later. For more information, see Secure ASP.NET Core Blazor WebAssembly.

3. The remaining defaults for the app are acceptable for this experience.
4. Select the **Save** button if you made changes.

In **Home** > **Azure AD B2C** > **User flows**:

Create a sign-up and sign-in user flow

At a minimum, select the **Application claims** > **Display Name** user attribute to populate the `context.User.Identity?.Name` / `context.User.Identity.Name` in the `LoginDisplay` component (`Shared/LoginDisplay.razor`).

Record the sign-up and sign-in user flow name created for the app (for example, `B2C_1_signupsignin`).

Create the Blazor app

In an empty folder, replace the placeholders in the following command with the information recorded earlier and execute the command in a command shell:

.NET CLI

```
dotnet new blazorwasm -au IndividualB2C --aad-b2c-instance "{AAD B2C
INSTANCE}" --client-id "{CLIENT ID}" --domain "{TENANT DOMAIN}" -o {PROJECT
NAME} -ssp "{SIGN UP OR SIGN IN POLICY}"
```

Expand table

Placeholder	Azure portal name	Example
`{AAD B2C INSTANCE}`	Instance	`https://contoso.b2clogin.com/` (includes the trailing slash)
`{PROJECT NAME}`	—	`BlazorSample`
`{CLIENT ID}`	Application (client) ID	`00001111-aaaa-2222-bbbb-3333cccc4444`
`{SIGN UP OR SIGN IN POLICY}`	Sign-up/sign-in user flow	`B2C_1_signupsignin1`
`{TENANT DOMAIN}`	Primary/Publisher/Tenant domain	`contoso.onmicrosoft.com`

The output location specified with the `-o|--output` option creates a project folder if it doesn't exist and becomes part of the project's name.

Add a pair of MsalProviderOptions for `openid` and `offline_access` DefaultAccessTokenScopes:

```
C#

builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("openid");
    options.ProviderOptions.DefaultAccessTokenScopes.Add("offline_access");
});
```

After creating the app, you should be able to:

- Log into the app using an Microsoft Entra ID user account.
- Request access tokens for Microsoft APIs. For more information, see:
  - Access token scopes
  - Quickstart: Configure an application to expose web APIs.

Run the app

Use one of the following approaches to run the app:

- Visual Studio
  - Select the **Run** button.
  - Use **Debug** > **Start Debugging** from the menu.
  - Press `F5`.
- .NET CLI command shell: Execute the `dotnet watch` (or `dotnet run`) command from the app's folder.

Parts of the app

This section describes the parts of an app generated from the Blazor WebAssembly project template and how the app is configured. There's no specific guidance to follow in this section for a basic working application if you created the app using the guidance in the Walkthrough section. The guidance in this section is helpful for updating an app to authenticate and authorize users. However, an alternative approach to updating an app is to create a new app from the guidance in the Walkthrough section and moving the app's components, classes, and resources to the new app.

Authentication package

When an app is created to use an Individual B2C Account (`IndividualB2C`), the app automatically receives a package reference for the Microsoft Authentication Library (Microsoft.Authentication.WebAssembly.Msal). The package provides a set of primitives that help the app authenticate users and obtain tokens to call protected APIs.

If adding authentication to an app, manually add the Microsoft.Authentication.WebAssembly.Msal package to the app.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

The Microsoft.Authentication.WebAssembly.Msal package transitively adds the Microsoft.AspNetCore.Components.WebAssembly.Authentication package to the app.

Authentication service support

Support for authenticating users is registered in the service container with the AddMsalAuthentication extension method provided by the Microsoft.Authentication.WebAssembly.Msal package. This method sets up all of the services required for the app to interact with the Identity Provider (IP).

In the `Program` file:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    builder.Configuration.Bind("AzureAdB2C",
options.ProviderOptions.Authentication);
});
```

The AddMsalAuthentication method accepts a callback to configure the parameters required to authenticate an app. The values required for configuring the app can be obtained from the configuration when you register the app.

Configuration is supplied by the `wwwroot/appsettings.json` file:

JSON

```
{
  "AzureAdB2C": {
    "Authority": "{AAD B2C INSTANCE}{TENANT DOMAIN}/{SIGN UP OR SIGN IN
POLICY}",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": false
  }
}
```

In the preceding configuration, the `{AAD B2C INSTANCE}` includes a trailing slash.

Example:

JSON

```
{
  "AzureAdB2C": {
    "Authority":
"https://contoso.b2clogin.com/contoso.onmicrosoft.com/B2C_1_signupsignin1",
    "ClientId": "00001111-aaaa-2222-bbbb-3333cccc4444",
    "ValidateAuthority": false
  }
}
```

Access token scopes

The Blazor WebAssembly template doesn't automatically configure the app to request an access token for a secure API. To provision an access token as part of the sign-in flow, add the scope to the default access token scopes of the MsalProviderOptions:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.DefaultAccessTokenScopes.Add("{SCOPE URI}");
});
```

Specify additional scopes with `AdditionalScopesToConsent`:

C#

```
options.ProviderOptions.AdditionalScopesToConsent.Add("{ADDITIONAL SCOPE
URI}");
```

> **Note**
>
> AdditionalScopesToConsent isn't able to provision delegated user permissions for Microsoft Graph via the Microsoft Entra ID consent UI when a user first uses an app registered in Microsoft Azure. For more information, see Use Graph API with ASP.NET Core Blazor WebAssembly.

For more information, see the following sections of the *Additional scenarios* article:

- Request additional access tokens
- Attach tokens to outgoing requests

Login mode

The framework defaults to pop-up login mode and falls back to redirect login mode if a pop-up can't be opened. Configure MSAL to use redirect login mode by setting the `LoginMode` property of MsalProviderOptions to `redirect`:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...
    options.ProviderOptions.LoginMode = "redirect";
});
```

The default setting is `popup`, and the string value isn't case-sensitive.

Imports file

The Microsoft.AspNetCore.Components.Authorization namespace is made available throughout the app via the `_Imports.razor` file:

razor

```
@using System.Net.Http
@using System.Net.Http.Json
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.Web
@using Microsoft.AspNetCore.Components.Web.Virtualization
@using Microsoft.AspNetCore.Components.WebAssembly.Http
@using Microsoft.JSInterop
```

```
@using {APPLICATION ASSEMBLY}
@using {APPLICATION ASSEMBLY}.Shared
```

Index page

The Index page (`wwwroot/index.html`) page includes a script that defines the `AuthenticationService` in JavaScript. `AuthenticationService` handles the low-level details of the OIDC protocol. The app internally calls methods defined in the script to perform the authentication operations.

HTML

```
<script
src="_content/Microsoft.Authentication.WebAssembly.Msal/AuthenticationServic
e.js"></script>
```

App component

The `App` component (`App.razor`) is similar to the `App` component found in Blazor Server apps:

- The AuthorizeRouteView component makes sure that the current user is authorized to access a given page or otherwise renders the `RedirectToLogin` component.
- The `RedirectToLogin` component manages redirecting unauthorized users to the login page.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `App` component (`App.razor`) isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to use. Inspect the `App` component (`App.razor`) in the generated app.
- Inspect the `App` component (`App.razor`) in reference source. Select the version from the branch selector, and search for the component in the `ProjectTemplates` folder of the repository because it has moved over the years.

> **Note**

> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

RedirectToLogin component

The `RedirectToLogin` component (`RedirectToLogin.razor`):

- Manages redirecting unauthorized users to the login page.
- The current URL that the user is attempting to access is maintained by so that they can be returned to that page if authentication is successful using:
  - Navigation history state in ASP.NET Core in .NET 7 or later.
  - A query string in ASP.NET Core in .NET 6 or earlier.

Inspect the `RedirectToLogin` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

LoginDisplay component

The `LoginDisplay` component (`LoginDisplay.razor`) is rendered in the `MainLayout` component (`MainLayout.razor`) and manages the following behaviors:

- For authenticated users:
  - Displays the current user name.
  - Offers a link to the user profile page in ASP.NET Core Identity.
  - Offers a button to log out of the app.
- For anonymous users:
  - Offers the option to register.
  - Offers the option to log in.

Due to changes in the framework across releases of ASP.NET Core, Razor markup for the `LoginDisplay` component isn't shown in this section. To inspect the markup of the component for a given release, use ***either*** of the following approaches:

- Create an app provisioned for authentication from the default Blazor WebAssembly project template for the version of ASP.NET Core that you intend to use. Inspect the `LoginDisplay` component in the generated app.
- Inspect the `LoginDisplay` component in reference source. The location of the component changed over time, so use GitHub search tools to locate the component. The templated content for `Hosted` equal to `true` is used.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Authentication component

The page produced by the `Authentication` component (`Pages/Authentication.razor`) defines the routes required for handling different authentication stages.

The RemoteAuthenticatorView component:

- Is provided by the Microsoft.AspNetCore.Components.WebAssembly.Authentication package.
- Manages performing the appropriate actions at each stage of authentication.

razor

```razor
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code {
    [Parameter]
    public string? Action { get; set; }
}
```

> **Note**
>
> Nullable reference types (NRTs) and .NET compiler null-state static analysis is supported in ASP.NET Core in .NET 6 or later. Prior to the release of ASP.NET Core in .NET 6, the `string` type appears without the null type designation (`?`).

Custom policies

The Microsoft Authentication Library (Microsoft.Authentication.WebAssembly.Msal, NuGet package) doesn't support AAD B2C custom policies.

Troubleshoot

Logging

To enable debug or trace logging for Blazor WebAssembly authentication, see the *Client-side authentication logging* section of ASP.NET Core Blazor logging with the article version selector set to ASP.NET Core 7.0 or later.

Common errors

- Misconfiguration of the app or Identity Provider (IP)

  The most common errors are caused by incorrect configuration. The following are a few examples:
  - Depending on the requirements of the scenario, a missing or incorrect Authority, Instance, Tenant ID, Tenant domain, Client ID, or Redirect URI prevents an app from authenticating clients.
  - Incorrect request scopes prevent clients from accessing server web API endpoints.
  - Incorrect or missing server API permissions prevent clients from accessing server web API endpoints.
  - Running the app at a different port than is configured in the Redirect URI of the IP's app registration. Note that a port isn't required for Microsoft Entra ID and an app running at a `localhost` development testing address, but the app's port configuration and the port where the app is running must match for non-`localhost` addresses.

Configuration sections of this article's guidance show examples of the correct configuration. Carefully check each section of the article looking for app and IP misconfiguration.

If the configuration appears correct:

- Analyze application logs.
- Examine the network traffic between the client app and the IP or server app with the browser's developer tools. Often, an exact error message or a message with a clue to what's causing the problem is returned to the client by the IP or server app after making a request. Developer tools guidance is found in the following articles:
  - Google Chrome (Google documentation)
  - Microsoft Edge
  - Mozilla Firefox (Mozilla documentation)
- For releases of Blazor where a JSON Web Token (JWT) is used, decode the contents of the token used for authenticating a client or accessing a server web API, depending on where the problem is occurring. For more information, see Inspect the content of a JSON Web Token (JWT).

The documentation team responds to document feedback and bugs in articles (open an issue from the **This page** feedback section) but is unable to provide product support. Several public support forums are available to assist with troubleshooting an app. We recommend the following:

- Stack Overflow (tag: blazor)
- ASP.NET Core Slack Team
- Blazor Gitter

The preceding forums are not owned or controlled by Microsoft.

For non-security, non-sensitive, and non-confidential reproducible framework bug reports, open an issue with the ASP.NET Core product unit. Don't open an issue with the product unit until you've thoroughly investigated the cause of a problem and can't resolve it on your own and with the help of the community on a public support forum. The product unit isn't able to troubleshoot individual apps that are broken due to simple misconfiguration or use cases involving third-party services. If a report is sensitive or confidential in nature or describes a potential security flaw in the product that cyberattackers may exploit, see Reporting security issues and bugs (dotnet/aspnetcore GitHub repository).

- Unauthorized client for ME-ID

> info: Microsoft.AspNetCore.Authorization.DefaultAuthorizationService[2]
> Authorization failed. These requirements were not met:
> DenyAnonymousAuthorizationRequirement: Requires an authenticated user.

Login callback error from ME-ID:

- Error: `unauthorized_client`
- Description: `AADB2C90058: The provided application is not configured to allow public clients.`

To resolve the error:

1. In the Azure portal, access the app's manifest.
2. Set the allowPublicClient attribute to `null` or `true`.

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE for any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in InPrivate or Incognito mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`

    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in InPrivate or Incognito mode. Some browsers require the URL of the app.
    - Microsoft Edge: Use `-inprivate`.
    - Google Chrome: Use `--incognito --new-window {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
    - Mozilla Firefox: Use `-private -url {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.
  - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
  - Make sure that the browser is closed by the IDE for any change to the app, test user, or provider configuration.

App upgrades

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Clear the local system's NuGet package caches by executing dotnet nuget locals all --clear from a command shell.
2. Delete the project's `bin` and `obj` folders.
3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

> **Note**
>
> Use of package versions incompatible with the app's target framework isn't supported. For information on a package, use the NuGet Gallery or FuGet Package Explorer.

Inspect the user

The following `User` component can be used directly in apps or serve as the basis for further customization.

`User.razor`:

razor

```razor
@page "/user"
@attribute [Authorize]
@using System.Text.Json
@using System.Security.Claims
@inject IAccessTokenProvider AuthorizationService

<h1>@AuthenticatedUser?.Identity?.Name</h1>

<h2>Claims</h2>

@foreach (var claim in AuthenticatedUser?.Claims ?? Array.Empty<Claim>())
{
    <p class="claim">@(claim.Type): @claim.Value</p>
}

<h2>Access token</h2>

<p id="access-token">@AccessToken?.Value</p>

<h2>Access token claims</h2>

@foreach (var claim in GetAccessTokenClaims())
{
    <p>@(claim.Key): @claim.Value.ToString()</p>
}

@if (AccessToken != null)
{
    <h2>Access token expires</h2>

    <p>Current time: <span id="current-time">@DateTimeOffset.Now</span></p>
    <p id="access-token-expires">@AccessToken.Expires</p>

    <h2>Access token granted scopes (as reported by the API)</h2>

    @foreach (var scope in AccessToken.GrantedScopes)
    {
        <p>Scope: @scope</p>
    }
}

@code {
    [CascadingParameter]
    private Task<AuthenticationState> AuthenticationState { get; set; }

    public ClaimsPrincipal AuthenticatedUser { get; set; }
```

```
    public AccessToken AccessToken { get; set; }

    protected override async Task OnInitializedAsync()
    {
        await base.OnInitializedAsync();
        var state = await AuthenticationState;
        var accessTokenResult = await
AuthorizationService.RequestAccessToken();

        if (!accessTokenResult.TryGetToken(out var token))
        {
            throw new InvalidOperationException(
                "Failed to provision the access token.");
        }

        AccessToken = token;

        AuthenticatedUser = state.User;
    }

    protected IDictionary<string, object> GetAccessTokenClaims()
    {
        if (AccessToken == null)
        {
            return new Dictionary<string, object>();
        }

        // header.payload.signature
        var payload = AccessToken.Value.Split(".")[1];
        var base64Payload = payload.Replace('-', '+').Replace('_', '/')
            .PadRight(payload.Length + (4 - payload.Length % 4) % 4, '=');

        return JsonSerializer.Deserialize<IDictionary<string, object>>(
            Convert.FromBase64String(base64Payload));
    }
}
```

Inspect the content of a JSON Web Token (JWT)

To decode a JSON Web Token (JWT), use Microsoft's jwt.ms tool. Values in the UI never leave your browser.

Example encoded JWT (shortened for display):

> eyJ0eXAiOiJKV1QiLCJhbGciOiJSUzI1NiIsImtpZCI6Ilg1ZVhrNHh5b2pORnVtMWtsMll0djhkbE5QNC1j ...
> bQdHBHGcQQRbW7Wmo6SWYG4V_bU55Ug_PW4pLPr20tTS8Ct7_uwy9DWrzCMzpD-EiwT5IjXwlGX3IXVjHIlX50IVIydBoPQtadvT7saKo1G5Jmutgq41o-dmz6-yBMKV2_nXA25Q

Example JWT decoded by the tool for an app that authenticates against Azure AAD B2C:

JSON

```
{
  "typ": "JWT",
  "alg": "RS256",
  "kid": "X5eXk4xyojNFum1kl2Ytv8dlNP4-c57dO6QGTVBwaNk"
}.{

ASP.NET Core Blazor WebAssembly additional security scenarios

Article • 10/08/2024

> **Important**

> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes additional security scenarios for Blazor WebAssembly apps.

Attach tokens to outgoing requests

AuthorizationMessageHandler is a DelegatingHandler used to process access tokens. Tokens are acquired using the IAccessTokenProvider service, which is registered by the framework. If a token can't be acquired, an AccessTokenNotAvailableException is thrown. AccessTokenNotAvailableException has a Redirect method that navigates to AccessTokenResult.InteractiveRequestUrl using the given AccessTokenResult.InteractionOptions to allow refreshing the access token.

For convenience, the framework provides the BaseAddressAuthorizationMessageHandler preconfigured with the app's base address as an authorized URL. **Access tokens are only added when the request URI is within the app's base URI.** When outgoing request URIs aren't within the app's base URI, use a custom AuthorizationMessageHandler class (*recommended*) or configure the AuthorizationMessageHandler.

> **Note**
>
> In addition to the client app configuration for server API access, the server API must also allow cross-origin requests (CORS) when the client and the server don't reside at the same base address. For more information on server-side CORS configuration, see the Cross-Origin Resource Sharing (CORS) section later in this article.

In the following example:

- AddHttpClient adds IHttpClientFactory and related services to the service collection and configures a named HttpClient (`WebAPI`). HttpClient.BaseAddress is the base address of the resource URI when sending requests. IHttpClientFactory is provided by the Microsoft.Extensions.Http NuGet package.
- BaseAddressAuthorizationMessageHandler is the DelegatingHandler used to process access tokens. Access tokens are only added when the request URI is within the app's base URI.
- IHttpClientFactory.CreateClient creates and configures an HttpClient instance for outgoing requests using the configuration that corresponds to the named HttpClient (`WebAPI`).

In the following example, HttpClientFactoryServiceCollectionExtensions.AddHttpClient is an extension in Microsoft.Extensions.Http. Add the package to an app that doesn't already reference it.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

C#

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddHttpClient("WebAPI",
        client => client.BaseAddress = new
Uri("https://api.contoso.com/v1.0"))
    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();

builder.Services.AddScoped(sp => sp.GetRequiredService<IHttpClientFactory>()
    .CreateClient("WebAPI"));
```

The configured HttpClient is used to make authorized requests using the try-catch pattern:

razor

```
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject HttpClient Http

...
```

```
protected override async Task OnInitializedAsync()
{
    try
    {
        var examples =
            await Http.GetFromJsonAsync<ExampleType[]>("ExampleAPIMethod");

        ...
    }
    catch (AccessTokenNotAvailableException exception)
    {
        exception.Redirect();
    }
}
```

Custom authentication request scenarios

The following scenarios demonstrate how to customize authentication requests and how to obtain the login path from authentication options.

Customize the login process

Manage additional parameters to a login request with the following methods one or more times on a new instance of InteractiveRequestOptions:

- TryAddAdditionalParameter
- TryRemoveAdditionalParameter
- TryGetAdditionalParameter

In the following `LoginDisplay` component example, additional parameters are added to the login request:

- `prompt` is set to `login`: Forces the user to enter their credentials on that request, negating single sign on.
- `loginHint` is set to `peter@contoso.com`: Pre-fills the username/email address field of the sign-in page for the user to `peter@contoso.com`. Apps often use this parameter during re-authentication, having already extracted the username from a previous sign in using the `preferred_username` claim.

`Shared/LoginDisplay.razor`:

C#

```
@using Microsoft.AspNetCore.Components.Authorization
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject NavigationManager Navigation

<AuthorizeView>
    <Authorized>
        Hello, @context.User.Identity?.Name!
        <button @onclick="BeginLogOut">Log out</button>
    </Authorized>
    <NotAuthorized>
        <button @onclick="BeginLogIn">Log in</button>
    </NotAuthorized>
</AuthorizeView>

@code{
    public void BeginLogOut()
    {
        Navigation.NavigateToLogout("authentication/logout");
    }

    public void BeginLogIn()
    {
        InteractiveRequestOptions requestOptions =
            new()
            {
                Interaction = InteractionType.SignIn,
                ReturnUrl = Navigation.Uri,
            };

        requestOptions.TryAddAdditionalParameter("prompt", "login");
        requestOptions.TryAddAdditionalParameter("loginHint",
"peter@contoso.com");

        Navigation.NavigateToLogin("authentication/login", requestOptions);
    }
}
```

For more information, see the following resources:

- InteractiveRequestOptions
- Popup request parameter list

Customize options before obtaining a token interactively

If an AccessTokenNotAvailableException occurs, manage additional parameters for a new identity provider access token request with the following methods one or more times on a new instance of InteractiveRequestOptions:

- TryAddAdditionalParameter

- TryRemoveAdditionalParameter
- TryGetAdditionalParameter

In the following example that obtains JSON data via web API, additional parameters are added to the redirect request if an access token isn't available (AccessTokenNotAvailableException is thrown):

- `prompt` is set to `login`: Forces the user to enter their credentials on that request, negating single sign on.
- `loginHint` is set to `peter@contoso.com`: Pre-fills the username/email address field of the sign-in page for the user to `peter@contoso.com`. Apps often use this parameter during re-authentication, having already extracted the username from a previous sign in using the `preferred_username` claim.

C#

```
try
{
    var examples = await Http.GetFromJsonAsync<ExampleType[]>
("ExampleAPIMethod");

    ...
}
catch (AccessTokenNotAvailableException ex)
{
    ex.Redirect(requestOptions => {
        requestOptions.TryAddAdditionalParameter("prompt", "login");
        requestOptions.TryAddAdditionalParameter("loginHint",
"peter@contoso.com");
    });
}
```

The preceding example assumes that:

- The presence of an `@using`/`using` statement for API in the Microsoft.AspNetCore.Components.WebAssembly.Authentication namespace.
- `HttpClient` injected as `Http`.

For more information, see the following resources:

- InteractiveRequestOptions
- Redirect request parameter list

Customize options when using an `IAccessTokenProvider`

If obtaining a token fails when using an IAccessTokenProvider, manage additional parameters for a new identity provider access token request with the following methods one or more times on a new instance of InteractiveRequestOptions:

- TryAddAdditionalParameter
- TryRemoveAdditionalParameter
- TryGetAdditionalParameter

In the following example that attempts to obtain an access token for the user, additional parameters are added to the login request if the attempt to obtain a token fails when TryGetToken is called:

- `prompt` is set to `login`: Forces the user to enter their credentials on that request, negating single sign on.
- `loginHint` is set to `peter@contoso.com`: Pre-fills the username/email address field of the sign-in page for the user to `peter@contoso.com`. Apps often use this parameter during re-authentication, having already extracted the username from a previous sign in using the `preferred_username` claim.

C#

```
var tokenResult = await TokenProvider.RequestAccessToken(
    new AccessTokenRequestOptions
    {
        Scopes = new[] { ... }
    });

if (!tokenResult.TryGetToken(out var token))
{
    tokenResult.InteractionOptions.TryAddAdditionalParameter("prompt",
"login");
    tokenResult.InteractionOptions.TryAddAdditionalParameter("loginHint",
        "peter@contoso.com");

    Navigation.NavigateToLogin(accessTokenResult.InteractiveRequestUrl,
        accessTokenResult.InteractionOptions);
}
```

The preceding example assumes:

- The presence of an `@using`/`using` statement for API in the Microsoft.AspNetCore.Components.WebAssembly.Authentication namespace.
- IAccessTokenProvider injected as `TokenProvider`.

For more information, see the following resources:

- InteractiveRequestOptions

- Popup request parameter list

Logout with a custom return URL

The following example logs out the user and returns the user to the `/goodbye` endpoint:

```
C#

Navigation.NavigateToLogout("authentication/logout", "goodbye");
```

Obtain the login path from authentication options

Obtain the configured login path from RemoteAuthenticationOptions:

```
C#

var loginPath =

RemoteAuthOptions.Get(Options.DefaultName).AuthenticationPaths.LogInPath;
```

The preceding example assumes:

- The presence of an `@using`/`using` statement for API in the following namespaces:
  - Microsoft.AspNetCore.Components.WebAssembly.Authentication
  - Microsoft.Extensions.Options
- `IOptionsSnapshot<RemoteAuthenticationOptions<ApiAuthorizationProviderOptions>>` injected as `RemoteAuthOptions`.

Custom `AuthorizationMessageHandler` class

This guidance in this section is recommended for client apps that make outgoing requests to URIs that aren't within the app's base URI.

In the following example, a custom class extends AuthorizationMessageHandler for use as the DelegatingHandler for an HttpClient. ConfigureHandler configures this handler to authorize outbound HTTP requests using an access token. The access token is only attached if at least one of the authorized URLs is a base of the request URI (HttpRequestMessage.RequestUri).

```
C#

using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
```

```
public class CustomAuthorizationMessageHandler : AuthorizationMessageHandler
{
    public CustomAuthorizationMessageHandler(IAccessTokenProvider provider,
        NavigationManager navigation)
        : base(provider, navigation)
    {
        ConfigureHandler(
            authorizedUrls: [ "https://api.contoso.com/v1.0" ],
            scopes: [ "example.read", "example.write" ]);
    }
}
```

In the preceding code, the scopes `example.read` and `example.write` are generic examples not meant to reflect valid scopes for any particular provider.

In the `Program` file, `CustomAuthorizationMessageHandler` is registered as a transient service and is configured as the DelegatingHandler for outgoing HttpResponseMessage instances made by a named HttpClient.

In the following example, HttpClientFactoryServiceCollectionExtensions.AddHttpClient is an extension in Microsoft.Extensions.Http. Add the package to an app that doesn't already reference it.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

C#

```
builder.Services.AddTransient<CustomAuthorizationMessageHandler>();

builder.Services.AddHttpClient("WebAPI",
        client => client.BaseAddress = new
Uri("https://api.contoso.com/v1.0"))
    .AddHttpMessageHandler<CustomAuthorizationMessageHandler>();
```

> **Note**
>
> In the preceding example, the `CustomAuthorizationMessageHandler` DelegatingHandler is registered as a transient service for AddHttpMessageHandler. Transient registration is recommended for

IHttpClientFactory, which manages its own DI scopes. For more information, see the following resources:

- Utility base component classes to manage a DI scope
- Detect client-side transient disposables

The configured HttpClient is used to make authorized requests using the try-catch pattern. Where the client is created with CreateClient (Microsoft.Extensions.Http package), the HttpClient is supplied instances that include access tokens when making requests to the server API. If the request URI is a relative URI, as it is in the following example (`ExampleAPIMethod`), it's combined with the BaseAddress when the client app makes the request:

razor

```
@inject IHttpClientFactory ClientFactory

...

@code {
    protected override async Task OnInitializedAsync()
    {
        try
        {
            var client = ClientFactory.CreateClient("WebAPI");

            var examples =
                await client.GetFromJsonAsync<ExampleType[]>
("ExampleAPIMethod");

            ...
        }
        catch (AccessTokenNotAvailableException exception)
        {
            exception.Redirect();
        }
    }
}
```

Configure `AuthorizationMessageHandler`

AuthorizationMessageHandler can be configured with authorized URLs, scopes, and a return URL using the ConfigureHandler method. ConfigureHandler configures the handler to authorize outbound HTTP requests using an access token. The access token is only attached if at least one of the authorized URLs is a base of the request URI

(HttpRequestMessage.RequestUri). If the request URI is a relative URI, it's combined with the BaseAddress.

In the following example, AuthorizationMessageHandler configures an HttpClient in the `Program` file:

C#

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddScoped(sp => new HttpClient(
    sp.GetRequiredService<AuthorizationMessageHandler>()
    .ConfigureHandler(
        authorizedUrls: [ "https://api.contoso.com/v1.0" ],
        scopes: [ "example.read", "example.write" ])
    .InnerHandler = new HttpClientHandler())
{
    BaseAddress = new Uri("https://api.contoso.com/v1.0")
});
```

In the preceding code, the scopes `example.read` and `example.write` are generic examples not meant to reflect valid scopes for any particular provider.

Typed `HttpClient`

A typed client can be defined that handles all of the HTTP and token acquisition concerns within a single class.

`WeatherForecastClient.cs`:

C#

```
using System.Net.Http.Json;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using static {ASSEMBLY NAME}.Data;

public class WeatherForecastClient(HttpClient http)
{
    private WeatherForecast[]? forecasts;

    public async Task<WeatherForecast[]> GetForecastAsync()
    {
        try
        {
            forecasts = await http.GetFromJsonAsync<WeatherForecast[]>(
                "WeatherForecast");
```

```
        }
        catch (AccessTokenNotAvailableException exception)
        {
            exception.Redirect();
        }

        return forecasts ?? Array.Empty<WeatherForecast>();
    }
}
```

In the preceding example, the `WeatherForecast` type is a static class that holds weather forecast data. The `{ASSEMBLY NAME}` placeholder is the app's assembly name (for example, `using static BlazorSample.Data;`).

In the following example, HttpClientFactoryServiceCollectionExtensions.AddHttpClient is an extension in Microsoft.Extensions.Http. Add the package to an app that doesn't already reference it.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

In the `Program` file:

C#

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddHttpClient<WeatherForecastClient>(
        client => client.BaseAddress = new
Uri("https://api.contoso.com/v1.0"))
    .AddHttpMessageHandler<BaseAddressAuthorizationMessageHandler>();
```

In a component that fetches weather data:

razor

```
@inject WeatherForecastClient Client

...

protected override async Task OnInitializedAsync()
```

```
{
    forecasts = await Client.GetForecastAsync();
}
```

Configure the `HttpClient` handler

The handler can be further configured with ConfigureHandler for outbound HTTP requests.

In the following example, HttpClientFactoryServiceCollectionExtensions.AddHttpClient is an extension in Microsoft.Extensions.Http. Add the package to an app that doesn't already reference it.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

In the `Program` file:

C#

```
builder.Services.AddHttpClient<WeatherForecastClient>(
        client => client.BaseAddress = new
Uri("https://api.contoso.com/v1.0"))
    .AddHttpMessageHandler(sp =>
sp.GetRequiredService<AuthorizationMessageHandler>()
    .ConfigureHandler(
        authorizedUrls: new [] { "https://api.contoso.com/v1.0" },
        scopes: new[] { "example.read", "example.write" }));
```

In the preceding code, the scopes `example.read` and `example.write` are generic examples not meant to reflect valid scopes for any particular provider.

Unauthenticated or unauthorized web API requests in an app with a secure default client

An app that ordinarily uses a secure default HttpClient can also make unauthenticated or unauthorized web API requests by configuring a named HttpClient.

In the following example, HttpClientFactoryServiceCollectionExtensions.AddHttpClient is an extension in Microsoft.Extensions.Http. Add the package to an app that doesn't already reference it.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

In the `Program` file:

C#

```
builder.Services.AddHttpClient("WebAPI.NoAuthenticationClient",
    client => client.BaseAddress = new Uri("https://api.contoso.com/v1.0"));
```

The preceding registration is in addition to the existing secure default HttpClient registration.

A component creates the HttpClient from the IHttpClientFactory (Microsoft.Extensions.Http package) to make unauthenticated or unauthorized requests:

razor

```
@inject IHttpClientFactory ClientFactory

...

@code {
    protected override async Task OnInitializedAsync()
    {
        var client =
ClientFactory.CreateClient("WebAPI.NoAuthenticationClient");

        var examples = await client.GetFromJsonAsync<ExampleType[]>(
            "ExampleNoAuthentication");

        ...
    }
}
```

> **Note**

The controller in the server API, `ExampleNoAuthenticationController` for the preceding example, isn't marked with the [Authorize] attribute.

The decision whether to use a secure client or an insecure client as the default HttpClient instance is up to the developer. One way to make this decision is to consider the number of authenticated versus unauthenticated endpoints that the app contacts. If the majority of the app's requests are to secure API endpoints, use the authenticated HttpClient instance as the default. Otherwise, register the unauthenticated HttpClient instance as the default.

An alternative approach to using the IHttpClientFactory is to create a typed client for unauthenticated access to anonymous endpoints.

Request additional access tokens

Access tokens can be manually obtained by calling IAccessTokenProvider.RequestAccessToken. In the following example, an additional scope is required by an app for the default HttpClient. The Microsoft Authentication Library (MSAL) example configures the scope with `MsalProviderOptions`:

In the `Program` file:

C#

```
builder.Services.AddMsalAuthentication(options =>
{
    ...

    options.ProviderOptions.AdditionalScopesToConsent.Add("{CUSTOM SCOPE
1}");
    options.ProviderOptions.AdditionalScopesToConsent.Add("{CUSTOM SCOPE
2}");
}
```

The `{CUSTOM SCOPE 1}` and `{CUSTOM SCOPE 2}` placeholders in the preceding example are custom scopes.

> ⓘ Note
>
> AdditionalScopesToConsent isn't able to provision delegated user permissions for Microsoft Graph via the Microsoft Entra ID consent UI when a user first uses an app

registered in Microsoft Azure. For more information, see Use Graph API with ASP.NET Core Blazor WebAssembly.

The IAccessTokenProvider.RequestAccessToken method provides an overload that allows an app to provision an access token with a given set of scopes.

In a Razor component:

razor

```
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject IAccessTokenProvider TokenProvider

...

var tokenResult = await TokenProvider.RequestAccessToken(
    new AccessTokenRequestOptions
    {
        Scopes = new[] { "{CUSTOM SCOPE 1}", "{CUSTOM SCOPE 2}" }
    });

if (tokenResult.TryGetToken(out var token))
{
    ...
}
```

The `{CUSTOM SCOPE 1}` and `{CUSTOM SCOPE 2}` placeholders in the preceding example are custom scopes.

AccessTokenResult.TryGetToken returns:

- `true` with the `token` for use.
- `false` if the token isn't retrieved.

Cross-Origin Resource Sharing (CORS)

When sending credentials (authorization cookies/headers) on CORS requests, the `Authorization` header must be allowed by the CORS policy.

The following policy includes configuration for:

- Request origins (`http://localhost:5000`, `https://localhost:5001`).
- Any method (verb).
- `Content-Type` and `Authorization` headers. To allow a custom header (for example, `x-custom-header`), list the header when calling WithHeaders.

- Credentials set by client-side JavaScript code (`credentials` property set to `include`).

C#

```
app.UseCors(policy =>
    policy.WithOrigins("http://localhost:5000", "https://localhost:5001")
        .AllowAnyMethod()
        .WithHeaders(HeaderNames.ContentType, HeaderNames.Authorization,
            "x-custom-header")
        .AllowCredentials());
```

For more information, see Enable Cross-Origin Requests (CORS) in ASP.NET Core and the sample app's HTTP Request Tester component (`Components/HTTPRequestTester.razor`).

Handle token request errors

When a single-page application (SPA) authenticates a user using OpenID Connect (OIDC), the authentication state is maintained locally within the SPA and in the Identity Provider (IP) in the form of a session cookie that's set as a result of the user providing their credentials.

The tokens that the IP emits for the user typically are valid for short periods of time, about one hour normally, so the client app must regularly fetch new tokens. Otherwise, the user would be logged-out after the granted tokens expire. In most cases, OIDC clients are able to provision new tokens without requiring the user to authenticate again thanks to the authentication state or "session" that is kept within the IP.

There are some cases in which the client can't get a token without user interaction, for example, when for some reason the user explicitly logs out from the IP. This scenario occurs if a user visits `https://login.microsoftonline.com` and logs out. In these scenarios, the app doesn't know immediately that the user has logged out. Any token that the client holds might no longer be valid. Also, the client isn't able to provision a new token without user interaction after the current token expires.

These scenarios aren't specific to token-based authentication. They are part of the nature of SPAs. An SPA using cookies also fails to call a server API if the authentication cookie is removed.

When an app performs API calls to protected resources, you must be aware of the following:

- To provision a new access token to call the API, the user might be required to authenticate again.
- Even if the client has a token that seems to be valid, the call to the server might fail because the token was revoked by the user.

When the app requests a token, there are two possible outcomes:

- The request succeeds, and the app has a valid token.
- The request fails, and the app must authenticate the user again to obtain a new token.

When a token request fails, you need to decide whether you want to save any current state before you perform a redirection. Several approaches exist to store state with increasing levels of complexity:

- Store the current page state in session storage. During the OnInitializedAsync lifecycle method (OnInitializedAsync), check if state can be restored before continuing.
- Add a query string parameter and use that as a way to signal the app that it needs to re-hydrate the previously saved state.
- Add a query string parameter with a unique identifier to store data in session storage without risking collisions with other items.

Save app state before an authentication operation with session storage

The following example shows how to:

- Preserve state before redirecting to the login page.
- Recover the previous state after authentication using a query string parameter.

razor

```
...
@using System.Text.Json
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject IAccessTokenProvider TokenProvider
@inject IJSRuntime JS
@inject NavigationManager Navigation

<EditForm Model="User" OnSubmit="OnSaveAsync">
    <label>
        First Name:
        <InputText @bind-Value="User!.Name" />
    </label>
```

```
    <label>
        Last Name:
        <InputText @bind-Value="User!.LastName" />
    </label>
    <button type="submit">Save User</button>
</EditForm>

@code {
    public Profile User { get; set; } = new Profile();

    protected override async Task OnInitializedAsync()
    {
        var currentQuery = new Uri(Navigation.Uri).Query;

        if (currentQuery.Contains("state=resumeSavingProfile"))
        {
            var user = await JS.InvokeAsync<string>
("sessionStorage.getItem",
                "resumeSavingProfile");

            if (!string.IsNullOrEmpty(user))
            {
                User = JsonSerializer.Deserialize<Profile>(user);
            }
        }
    }

    public async Task OnSaveAsync()
    {
        var http = new HttpClient();
        http.BaseAddress = new Uri(Navigation.BaseUri);

        var resumeUri = Navigation.Uri + $"?state=resumeSavingProfile";

        var tokenResult = await TokenProvider.RequestAccessToken(
            new AccessTokenRequestOptions
            {
                ReturnUrl = resumeUri
            });

        if (tokenResult.TryGetToken(out var token))
        {
            http.DefaultRequestHeaders.Add("Authorization",
                $"Bearer {token.Value}");
            await http.PostAsJsonAsync("Save", User);
        }
        else
        {
            await JS.InvokeVoidAsync("sessionStorage.setItem",
                "resumeSavingProfile", JsonSerializer.Serialize(User));
            Navigation.NavigateTo(tokenResult.InteractiveRequestUrl);
        }
    }

    public class Profile
```

```
    {
        public string? FirstName { get; set; }
        public string? LastName { get; set; }
    }
}
```

Save app state before an authentication operation with session storage and a state container

During an authentication operation, there are cases where you want to save the app state before the browser is redirected to the IP. This can be the case when you're using a state container and want to restore the state after the authentication succeeds. You can use a custom authentication state object to preserve app-specific state or a reference to it and restore that state after the authentication operation successfully completes. The following example demonstrates the approach.

A state container class is created in the app with properties to hold the app's state values. In the following example, the container is used to maintain the counter value of the default Blazor project template's `Counter` component (`Counter.razor`). Methods for serializing and deserializing the container are based on System.Text.Json.

C#

```
using System.Text.Json;

public class StateContainer
{
    public int CounterValue { get; set; }

    public string GetStateForLocalStorage() =>
JsonSerializer.Serialize(this);

    public void SetStateFromLocalStorage(string locallyStoredState)
    {
        var deserializedState =
            JsonSerializer.Deserialize<StateContainer>(locallyStoredState);

        CounterValue = deserializedState.CounterValue;
    }
}
```

The `Counter` component uses the state container to maintain the `currentCount` value outside of the component:

razor

```razor
@page "/counter"
@inject StateContainer State

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    protected override void OnInitialized()
    {
        if (State.CounterValue > 0)
        {
            currentCount = State.CounterValue;
        }
    }

    private void IncrementCount()
    {
        currentCount++;
        State.CounterValue = currentCount;
    }
}
```

Create an `ApplicationAuthenticationState` from RemoteAuthenticationState. Provide an `Id` property, which serves as an identifier for the locally-stored state.

`ApplicationAuthenticationState.cs`:

C#

```
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class ApplicationAuthenticationState : RemoteAuthenticationState
{
    public string? Id { get; set; }
}
```

The `Authentication` component (`Authentication.razor`) saves and restores the app's state using local session storage with the `StateContainer` serialization and deserialization methods, `GetStateForLocalStorage` and `SetStateFromLocalStorage`:

razor

```
@page "/authentication/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication
@inject IJSRuntime JS
@inject StateContainer State

<RemoteAuthenticatorViewCore Action="Action"

TAuthenticationState="ApplicationAuthenticationState"
                             AuthenticationState="AuthenticationState"
                             OnLogInSucceeded="RestoreState"
                             OnLogOutSucceeded="RestoreState" />

@code {
    [Parameter]
    public string? Action { get; set; }

    public ApplicationAuthenticationState AuthenticationState { get; set; }
=
        new ApplicationAuthenticationState();

    protected override async Task OnInitializedAsync()
    {
        if
(RemoteAuthenticationActions.IsAction(RemoteAuthenticationActions.LogIn,
            Action) ||

RemoteAuthenticationActions.IsAction(RemoteAuthenticationActions.LogOut,
            Action))
        {
            AuthenticationState.Id = Guid.NewGuid().ToString();

            await JS.InvokeVoidAsync("sessionStorage.setItem",
                AuthenticationState.Id, State.GetStateForLocalStorage());
        }
    }

    private async Task RestoreState(ApplicationAuthenticationState state)
    {
        if (state.Id != null)
        {
            var locallyStoredState = await JS.InvokeAsync<string>(
                "sessionStorage.getItem", state.Id);

            if (locallyStoredState != null)
            {
                State.SetStateFromLocalStorage(locallyStoredState);
                await JS.InvokeVoidAsync("sessionStorage.removeItem",
state.Id);
            }
        }
    }
}
```

This example uses Microsoft Entra (ME-ID) for authentication. In the `Program` file:

- The `ApplicationAuthenticationState` is configured as the Microsoft Authentication Library (MSAL) `RemoteAuthenticationState` type.
- The state container is registered in the service container.

C#

```
builder.Services.AddMsalAuthentication<ApplicationAuthenticationState>
(options =>
{
    builder.Configuration.Bind("AzureAd",
options.ProviderOptions.Authentication);
});

builder.Services.AddSingleton<StateContainer>();
```

Customize app routes

The Microsoft.AspNetCore.Components.WebAssembly.Authentication library uses the routes shown in the following table for representing different authentication states.

Expand table

Route	Purpose
`authentication/login`	Triggers a sign-in operation.
`authentication/login-callback`	Handles the result of any sign-in operation.
`authentication/login-failed`	Displays error messages when the sign-in operation fails for some reason.
`authentication/logout`	Triggers a sign-out operation.
`authentication/logout-callback`	Handles the result of a sign-out operation.
`authentication/logout-failed`	Displays error messages when the sign-out operation fails for some reason.
`authentication/logged-out`	Indicates that the user has successfully logout.
`authentication/profile`	Triggers an operation to edit the user profile.
`authentication/register`	Triggers an operation to register a new user.

The routes shown in the preceding table are configurable via RemoteAuthenticationOptions<TRemoteAuthenticationProviderOptions>.AuthenticationPaths. When setting options to provide custom routes, confirm that the app has a route that handles each path.

In the following example, all of the paths are prefixed with `/security`.

`Authentication` component (`Authentication.razor`):

razor

```
@page "/security/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action" />

@code{
    [Parameter]
    public string? Action { get; set; }
}
```

In the `Program` file:

C#

```
builder.Services.AddApiAuthorization(options => {
    options.AuthenticationPaths.LogInPath = "security/login";
    options.AuthenticationPaths.LogInCallbackPath = "security/login-
callback";
    options.AuthenticationPaths.LogInFailedPath = "security/login-failed";
    options.AuthenticationPaths.LogOutPath = "security/logout";
    options.AuthenticationPaths.LogOutCallbackPath = "security/logout-
callback";
    options.AuthenticationPaths.LogOutFailedPath = "security/logout-failed";
    options.AuthenticationPaths.LogOutSucceededPath = "security/logged-out";
    options.AuthenticationPaths.ProfilePath = "security/profile";
    options.AuthenticationPaths.RegisterPath = "security/register";
});
```

If the requirement calls for completely different paths, set the routes as described previously and render the RemoteAuthenticatorView with an explicit action parameter:

razor

```
@page "/register"

<RemoteAuthenticatorView Action="RemoteAuthenticationActions.Register" />
```

You're allowed to break the UI into different pages if you choose to do so.

Customize the authentication user interface

RemoteAuthenticatorView includes a default set of UI fragments for each authentication state. Each state can be customized by passing in a custom RenderFragment. To customize the displayed text during the initial login process, can change the RemoteAuthenticatorView as follows.

`Authentication` component (`Authentication.razor`):

razor

```
@page "/security/{action}"
@using Microsoft.AspNetCore.Components.WebAssembly.Authentication

<RemoteAuthenticatorView Action="@Action">
    <LoggingIn>
        You are about to be redirected to https://login.microsoftonline.com.
    </LoggingIn>
</RemoteAuthenticatorView>

@code{
    [Parameter]
    public string? Action { get; set; }
}
```

The RemoteAuthenticatorView has one fragment that can be used per authentication route shown in the following table.

Expand table

Route	Fragment
`authentication/login`	`<LoggingIn>`
`authentication/login-callback`	`<CompletingLoggingIn>`
`authentication/login-failed`	`<LogInFailed>`
`authentication/logout`	`<LogOut>`
`authentication/logout-callback`	`<CompletingLogOut>`
`authentication/logout-failed`	`<LogOutFailed>`
`authentication/logged-out`	`<LogOutSucceeded>`

Route	Fragment
`authentication/profile`	`<UserProfile>`
`authentication/register`	`<Registering>`

Customize the user

Users bound to the app can be customized.

Customize the user with a payload claim

In the following example, the app's authenticated users receive an `amr` claim for each of the user's authentication methods. The `amr` claim identifies how the subject of the token was authenticated in Microsoft identity platform v1.0 payload claims. The example uses a custom user account class based on RemoteUserAccount.

Create a class that extends the RemoteUserAccount class. The following example sets the `AuthenticationMethod` property to the user's array of `amr` JSON property values. `AuthenticationMethod` is populated automatically by the framework when the user is authenticated.

C#

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

public class CustomUserAccount : RemoteUserAccount
{
    [JsonPropertyName("amr")]
    public string[]? AuthenticationMethod { get; set; }
}
```

Create a factory that extends AccountClaimsPrincipalFactory<TAccount> to create claims from the user's authentication methods stored in `CustomUserAccount.AuthenticationMethod`:

C#

```
using System.Security.Claims;
using Microsoft.AspNetCore.Components;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication.Internal;

public class CustomAccountFactory(NavigationManager navigation,
```

```
    IAccessTokenProviderAccessor accessor)
    : AccountClaimsPrincipalFactory<CustomUserAccount>(accessor)
{
    public override async ValueTask<ClaimsPrincipal> CreateUserAsync(
        CustomUserAccount account, RemoteAuthenticationUserOptions options)
    {
        var initialUser = await base.CreateUserAsync(account, options);

        if (initialUser.Identity != null &&
initialUser.Identity.IsAuthenticated)
        {
            var userIdentity = (ClaimsIdentity)initialUser.Identity;

            if (account.AuthenticationMethod is not null)
            {
                foreach (var value in account.AuthenticationMethod)
                {
                    userIdentity.AddClaim(new Claim("amr", value));
                }
            }
        }

        return initialUser;
    }
}
```

Register the `CustomAccountFactory` for the authentication provider in use. Any of the following registrations are valid:

- AddOidcAuthentication:

  C#

  ```
  using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

  ...

  builder.Services.AddOidcAuthentication<RemoteAuthenticationState,
      CustomUserAccount>(options =>
      {
          ...
      })
      .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
          CustomUserAccount, CustomAccountFactory>();
  ```

- AddMsalAuthentication:

  C#

  ```
  using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
  ```

```
...

builder.Services.AddMsalAuthentication<RemoteAuthenticationState,
    CustomUserAccount>(options =>
    {
        ...
    })
    .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
        CustomUserAccount, CustomAccountFactory>();
```

- AddApiAuthorization:

```
C#

using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

...

builder.Services.AddApiAuthorization<RemoteAuthenticationState,
    CustomUserAccount>(options =>
    {
        ...
    })
    .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
        CustomUserAccount, CustomAccountFactory>();
```

ME-ID security groups and roles with a custom user account class

For an additional example that works with ME-ID security groups and ME-ID Administrator Roles and a custom user account class, see ASP.NET Core Blazor WebAssembly with Microsoft Entra ID groups and roles.

Authenticate users to only call protected third party APIs

Authenticate the user with a client-side OAuth flow against the third-party API provider:

```
C#

builder.services.AddOidcAuthentication(options => { ... });
```

In this scenario:

- The server hosting the app doesn't play a role.
- APIs on the server can't be protected.
- The app can only call protected third-party APIs.

Authenticate users with a third-party provider and call protected APIs on the host server and the third party

Configure Identity with a third-party login provider. Obtain the tokens required for third-party API access and store them.

When a user logs in, Identity collects access and refresh tokens as part of the authentication process. At that point, there are a couple of approaches available for making API calls to third-party APIs.

Use a server access token to retrieve the third-party access token

Use the access token generated on the server to retrieve the third-party access token from a server API endpoint. From there, use the third-party access token to call third-party API resources directly from Identity on the client.

We don't recommend this approach. This approach requires treating the third-party access token as if it were generated for a public client. In OAuth terms, the public app doesn't have a client secret because it can't be trusted to store secrets safely, and the access token is produced for a confidential client. A confidential client is a client that has a client secret and is assumed to be able to safely store secrets.

- The third-party access token might be granted additional scopes to perform sensitive operations based on the fact that the third-party emitted the token for a more trusted client.
- Similarly, refresh tokens shouldn't be issued to a client that isn't trusted, as doing so gives the client unlimited access unless other restrictions are put into place.

Make API calls from the client to the server API in order to call third-party APIs

Make an API call from the client to the server API. From the server, retrieve the access token for the third-party API resource and issue whatever call is necessary.

We recommend this approach. While this approach requires an extra network hop through the server to call a third-party API, it ultimately results in a safer experience:

- The server can store refresh tokens and ensure that the app doesn't lose access to third-party resources.
- The app can't leak access tokens from the server that might contain more sensitive permissions.

Use OpenID Connect (OIDC) v2.0 endpoints

The authentication library and Blazor project templates use OpenID Connect (OIDC) v1.0 endpoints. To use a v2.0 endpoint, configure the JWT Bearer JwtBearerOptions.Authority option. In the following example, ME-ID is configured for v2.0 by appending a `v2.0` segment to the Authority property:

C#

```
using Microsoft.AspNetCore.Authentication.JwtBearer;

...

builder.Services.Configure<JwtBearerOptions>(
    JwtBearerDefaults.AuthenticationScheme,
    options =>
    {
        options.Authority += "/v2.0";
    });
```

Alternatively, the setting can be made in the app settings (`appsettings.json`) file:

JSON

```
{
  "Local": {
    "Authority": "https://login.microsoftonline.com/common/oauth2/v2.0/",
    ...
  }
}
```

If tacking on a segment to the authority isn't appropriate for the app's OIDC provider, such as with non-ME-ID providers, set the Authority property directly. Either set the property in JwtBearerOptions or in the app settings file (`appsettings.json`) with the `Authority` key.

The list of claims in the ID token changes for v2.0 endpoints. Microsoft documentation on the changes has been retired, but guidance on the claims in an ID token is available in the ID token claims reference.

Configure and use gRPC in components

To configure a Blazor WebAssembly app to use the ASP.NET Core gRPC framework:

- Enable gRPC-Web on the server. For more information, see gRPC-Web in ASP.NET Core gRPC apps.
- Register gRPC services for the app's message handler. The following example configures the app's authorization message handler to use the GreeterClient service from the gRPC tutorial (the `Program` file).

> **Note**
>
> Prerendering is enabled by default in Blazor Web Apps, so you must account for the component rendering first from the server and then from the client. Any prerendered state should flow to the client so that it can be reused. For more information, see Prerender ASP.NET Core Razor components.

C#

```
using System.Net.Http;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Grpc.Net.Client;
using Grpc.Net.Client.Web;

...

builder.Services.AddScoped(sp =>
{
    var baseAddressMessageHandler =
        sp.GetRequiredService<BaseAddressAuthorizationMessageHandler>();
    baseAddressMessageHandler.InnerHandler = new HttpClientHandler();
    var grpcWebHandler =
        new GrpcWebHandler(GrpcWebMode.GrpcWeb, baseAddressMessageHandler);
    var channel =
GrpcChannel.ForAddress(builder.HostEnvironment.BaseAddress,
        new GrpcChannelOptions { HttpHandler = grpcWebHandler });

    return new Greeter.GreeterClient(channel);
});
```

A component in the client app can make gRPC calls using the gRPC client (`Grpc.razor`):

razor

```
@page "/grpc"
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize]
@inject Greeter.GreeterClient GreeterClient

<h1>Invoke gRPC service</h1>

<p>
```

```
    <input @bind="name" placeholder="Type your name" />
    <button @onclick="GetGreeting" class="btn btn-primary">Call gRPC
service</button>
</p>

Server response: <strong>@serverResponse</strong>

@code {
    private string name = "Bert";
    private string? serverResponse;

    private async Task GetGreeting()
    {
        try
        {
            var request = new HelloRequest { Name = name };
            var reply = await GreeterClient.SayHelloAsync(request);
            serverResponse = reply.Message;
        }
        catch (Grpc.Core.RpcException ex)
            when (ex.Status.DebugException is
                AccessTokenNotAvailableException tokenEx)
        {
            tokenEx.Redirect();
        }
    }
}
```

To use the `Status.DebugException` property, use Grpc.Net.Client version 2.30.0 or later.

For more information, see gRPC-Web in ASP.NET Core gRPC apps.

Replace the `AuthenticationService` implementation

The following subsections explain how to replace:

- Any JavaScript `AuthenticationService` implementation.
- The Microsoft Authentication Library for JavaScript (`MSAL.js`).

Replace any JavaScript `AuthenticationService` implementation

Create a JavaScript library to handle your custom authentication details.

> ⚠ **Warning**

The guidance in this section is an implementation detail of the default RemoteAuthenticationService<TRemoteAuthenticationState,TAccount,TProviderOptions>. The TypeScript code in this section applies specifically to ASP.NET Core in .NET 7 and is subject to change without notice in upcoming releases of ASP.NET Core.

TypeScript

```
// .NET makes calls to an AuthenticationService object in the Window.
declare global {
  interface Window { AuthenticationService: AuthenticationService }
}

export interface AuthenticationService {
  // Init is called to initialize the AuthenticationService.
  public static init(settings: UserManagerSettings &
AuthorizeServiceSettings, logger: any) : Promise<void>;

  // Gets the currently authenticated user.
  public static getUser() : Promise<{[key: string] : string }>;

  // Tries to get an access token silently.
  public static getAccessToken(options: AccessTokenRequestOptions) :
Promise<AccessTokenResult>;

  // Tries to sign in the user or get an access token interactively.
  public static signIn(context: AuthenticationContext) :
Promise<AuthenticationResult>;

  // Handles the sign-in process when a redirect is used.
  public static async completeSignIn(url: string) :
Promise<AuthenticationResult>;

  // Signs the user out.
  public static signOut(context: AuthenticationContext) :
Promise<AuthenticationResult>;

  // Handles the signout callback when a redirect is used.
  public static async completeSignOut(url: string) :
Promise<AuthenticationResult>;
}

// The rest of these interfaces match their C# definitions.

export interface AccessTokenRequestOptions {
  scopes: string[];
  returnUrl: string;
}

export interface AccessTokenResult {
  status: AccessTokenResultStatus;
  token?: AccessToken;
```

```
}

export interface AccessToken {
  value: string;
  expires: Date;
  grantedScopes: string[];
}

export enum AccessTokenResultStatus {
  Success = 'Success',
  RequiresRedirect = 'RequiresRedirect'
}

export enum AuthenticationResultStatus {
  Redirect = 'Redirect',
  Success = 'Success',
  Failure = 'Failure',
  OperationCompleted = 'OperationCompleted'
};

export interface AuthenticationResult {
  status: AuthenticationResultStatus;
  state?: unknown;
  message?: string;
}

export interface AuthenticationContext {
  state?: unknown;
  interactiveRequest: InteractiveAuthenticationRequest;
}

export interface InteractiveAuthenticationRequest {
  scopes?: string[];
  additionalRequestParameters?: { [key: string]: any };
};
```

You can import the library by removing the original `<script>` tag and adding a `<script>` tag that loads the custom library. The following example demonstrates replacing the default `<script>` tag with one that loads a library named `CustomAuthenticationService.js` from the `wwwroot/js` folder.

In `wwwroot/index.html` before the Blazor script (`_framework/blazor.webassembly.js`) inside the closing `</body>` tag:

diff

```
- <script
src="_content/Microsoft.Authentication.WebAssembly.Msal/AuthenticationServic
e.js"></script>
+ <script src="js/CustomAuthenticationService.js"></script>
```

For more information, see AuthenticationService.ts in the dotnet/aspnetcore GitHub repository.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Replace the Microsoft Authentication Library for JavaScript (`MSAL.js`)

If an app requires a custom version of the Microsoft Authentication Library for JavaScript (MSAL.js), perform the following steps:

1. Confirm the system has the latest developer .NET SDK or obtain and install the latest developer SDK from .NET Core SDK: Installers and Binaries. Configuration of internal NuGet feeds isn't required for this scenario.
2. Set up the `dotnet/aspnetcore` GitHub repository for development following the documentation at Build ASP.NET Core from Source. Fork and clone or download a ZIP archive of the dotnet/aspnetcore GitHub repository.
3. Open the `src/Components/WebAssembly/Authentication.Msal/src/Interop/package.json` file and set the desired version of `@azure/msal-browser`. For a list of released versions, visit the @azure/msal-browser npm website and select the **Versions** tab.
4. Build the `Authentication.Msal` project in the `src/Components/WebAssembly/Authentication.Msal/src` folder with the `yarn build` command in a command shell.
5. If the app uses compressed assets (Brotli/Gzip), compress the `Interop/dist/Release/AuthenticationService.js` file.
6. Copy the `AuthenticationService.js` file and compressed versions (`.br`/`.gz`) of the file, if produced, from the `Interop/dist/Release` folder into the app's `publish/wwwroot/_content/Microsoft.Authentication.WebAssembly.Msal` folder in the app's published assets.

Pass custom provider options

Define a class for passing the data to the underlying JavaScript library.

> **ⓘ Important**
>
> The class's structure must match what the library expects when the JSON is serialized with System.Text.Json.

The following example demonstrates a `ProviderOptions` class with JsonPropertyName attributes matching a hypothetical custom provider library's expectations:

C#

```
public class ProviderOptions
{
    public string? Authority { get; set; }
    public string? MetadataUrl { get; set; }

    [JsonPropertyName("client_id")]
    public string? ClientId { get; set; }

    public IList<string> DefaultScopes { get; set; } = [ "openid", "profile"
];

    [JsonPropertyName("redirect_uri")]
    public string? RedirectUri { get; set; }

    [JsonPropertyName("post_logout_redirect_uri")]
    public string? PostLogoutRedirectUri { get; set; }

    [JsonPropertyName("response_type")]
    public string? ResponseType { get; set; }

    [JsonPropertyName("response_mode")]
    public string? ResponseMode { get; set; }
}
```

Register the provider options within the DI system and configure the appropriate values:

C#

```
builder.Services.AddRemoteAuthentication<RemoteAuthenticationState,
RemoteUserAccount,
    ProviderOptions>(options => {
        options.ProviderOptions.Authority = "...";
        options.ProviderOptions.MetadataUrl = "...";
        options.ProviderOptions.ClientId = "...";
        options.ProviderOptions.DefaultScopes = [ "openid", "profile",
"myApi" ];
        options.ProviderOptions.RedirectUri =
```

```
"https://localhost:5001/authentication/login-callback";
        options.ProviderOptions.PostLogoutRedirectUri =
"https://localhost:5001/authentication/logout-callback";
        options.ProviderOptions.ResponseType = "...";
        options.ProviderOptions.ResponseMode = "...";
    });
```

The preceding example sets redirect URIs with regular string literals. The following alternatives are available:

- TryCreate using IWebAssemblyHostEnvironment.BaseAddress:

  C#

  ```
  Uri.TryCreate(
      $"{builder.HostEnvironment.BaseAddress}authentication/login-
  callback",
      UriKind.Absolute, out var redirectUri);
  options.RedirectUri = redirectUri;
  ```

- Host builder configuration:

  C#

  ```
  options.RedirectUri = builder.Configuration["RedirectUri"];
  ```

  `wwwroot/appsettings.json`:

  JSON

  ```
  {
    "RedirectUri": "https://localhost:5001/authentication/login-callback"
  }
  ```

Microsoft Entra (ME-ID) groups, Administrator Roles, and App Roles

Article • 10/21/2024

This article explains how to configure Blazor WebAssembly to use Microsoft Entra ID (ME-ID) groups and roles.

ME-ID provides several authorization approaches that can be combined with ASP.NET Core Identity:

- Groups
  - Security
  - Microsoft 365
  - Distribution
- Roles
  - ME-ID built-in Administrator Roles
  - App Roles

The guidance in this article applies to the Blazor WebAssembly ME-ID deployment scenarios described in the following articles:

- Standalone with Microsoft Accounts
- Standalone with ME-ID

The examples in this article take advantage of new .NET/C# features. When using the examples with .NET 7 or earlier, minor modifications are required. However, the text and code examples that pertain to interacting with ME-ID and Microsoft Graph are the same for all versions of ASP.NET Core.

Sample app

Access the sample app, named `BlazorWebAssemblyEntraGroupsAndRoles`, through the latest version folder from the repository's root with the following link. The sample is provided for .NET 8 or later. See the sample app's `README` file for steps on how to run the app.

The sample app includes a `UserClaims` component for displaying a user's claims. The `UserData` component displays the user's basic account properties.

View or download sample code (how to download)

Prerequisite

The guidance in this article implements the Microsoft Graph API per the *Graph SDK* guidance in Use Graph API with ASP.NET Core Blazor WebAssembly. Follow the *Graph SDK* implementation guidance to configure the app and test it to confirm that the app can obtain Graph API data for a test user account. Additionally, see the Graph API article's security article cross-links to review Microsoft Graph security concepts.

When testing with the Graph SDK locally, we recommend using a new in-private/incognito browser session for each test to prevent lingering cookies from interfering with tests. For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID.

ME-ID app registration online tools

This article refers to the Azure portal throughout when prompting you to configure the app's ME-ID app registration, but the Microsoft Entra Admin Center is also a viable option for managing ME-ID app registrations. Either interface can be used, but the guidance in this article specifically covers gestures for the Azure portal.

Scopes

Permissions and *scopes* mean the same thing and are used interchangeably in security documentation and the Azure portal. Unless the text is referring to the Azure portal, this article uses *scope/scopes* when referring to Graph permissions.

Scopes are case insensitive, so `User.Read` is the same as `user.read`. Feel free to use either format, but we recommend a consistent choice across application code.

To permit Microsoft Graph API calls for user profile, role assignment, and group membership data, the app is configured with the ***delegated*** `User.Read` scope (`https://graph.microsoft.com/User.Read`) in the Azure portal because access to read user data is determined by the scopes granted (delegated) to individual users. This scope is required in addition to the scopes required in ME-ID deployment scenarios described by the articles listed earlier (*Standalone with Microsoft Accounts* or *Standalone with ME-ID*).

Additional required scopes include:

- ***Delegated*** RoleManagement.Read.Directory scope (`https://graph.microsoft.com/RoleManagement.Read.Directory`): Allows the app to

read the role-based access control (RBAC) settings for your company's directory, on behalf of the signed-in user. This includes reading directory role templates, directory roles, and memberships. Directory role memberships are used to create `directoryRole` claims in the app for ME-ID built-in Administrator Roles. Admin consent is required.

- ***Delegated*** AdministrativeUnit.Read.All scope (`https://graph.microsoft.com/AdministrativeUnit.Read.All`): Allows the app to read administrative units and administrative unit membership on behalf of the signed-in user. These memberships are used to create `administrativeUnit` claims in the app. Admin consent is required.

For more information, see Overview of permissions and consent in the Microsoft identity platform and Overview of Microsoft Graph permissions.

Custom user account

Assign users to ME-ID security groups and ME-ID Administrator Roles in the Azure portal.

The examples in this article:

- Assume that a user is assigned to the ME-ID *Billing Administrator* role in the Azure portal ME-ID tenant for authorization to access server API data.
- Use authorization policies to control access within the app.

Extend RemoteUserAccount to include properties for:

- `Roles`: ME-ID App Roles array (covered in the App Roles section)
- `Oid`: Immutable object identifier claim (oid) (uniquely identifies a user within and across tenants)

`CustomUserAccount.cs`:

C#

```
using System.Text.Json.Serialization;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;

namespace BlazorWebAssemblyEntraGroupsAndRoles;

public class CustomUserAccount : RemoteUserAccount
{
    [JsonPropertyName("roles")]
    public List<string>? Roles { get; set; }
```

```
    [JsonPropertyName("oid")]
    public string? Oid { get; set; }
}
```

Add a package reference to app for Microsoft.Graph.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Add the Graph SDK utility classes and configuration in the *Graph SDK* guidance of the Use Graph API with ASP.NET Core Blazor WebAssembly article. Specify the `User.Read`, `RoleManagement.Read.Directory`, and `AdministrativeUnit.Read.All` scopes for the access token as the article shows in its example `wwwroot/appsettings.json` file.

Add the following custom user account factory to the app. The custom user factory is used to establish:

- App Role claims (`role`) (covered in the App Roles section).
- Example user profile data claims for the user's mobile phone number (`mobilePhone`) and office location (`officeLocation`).
- ME-ID Administrator Role claims (`directoryRole`).
- ME-ID Administrative Unit claims (`administrativeUnit`).
- ME-ID Group claims (`directoryGroup`).
- An ILogger (`logger`) for convenience in case you wish to log information or errors.

`CustomAccountFactory.cs`:

C#

```
using System.Security.Claims;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication.Internal;
using Microsoft.Graph;
using Microsoft.Kiota.Abstractions.Authentication;

namespace BlazorWebAssemblyEntraGroupsAndRoles;

public class CustomAccountFactory(IAccessTokenProviderAccessor accessor,
```

```
        IServiceProvider serviceProvider, ILogger<CustomAccountFactory>
logger,
        IConfiguration config)
    : AccountClaimsPrincipalFactory<CustomUserAccount>(accessor)
{
    private readonly ILogger<CustomAccountFactory> logger = logger;
    private readonly IServiceProvider serviceProvider = serviceProvider;
    private readonly string? baseUrl = string.Join("/",
        config.GetSection("MicrosoftGraph")["BaseUrl"],
        config.GetSection("MicrosoftGraph")["Version"]);

    public override async ValueTask<ClaimsPrincipal> CreateUserAsync(
        CustomUserAccount account,
        RemoteAuthenticationUserOptions options)
    {
        var initialUser = await base.CreateUserAsync(account, options);

        if (initialUser.Identity is not null &&
            initialUser.Identity.IsAuthenticated)
        {
            var userIdentity = initialUser.Identity as ClaimsIdentity;

            if (userIdentity is not null && !string.IsNullOrEmpty(baseUrl)
&&
                account.Oid is not null)
            {
                account?.Roles?.ForEach((role) =>
                {
                    userIdentity.AddClaim(new Claim("role", role));
                });

                try
                {
                    var client = new GraphServiceClient(
                        new HttpClient(),
                        serviceProvider
                            .GetRequiredService<IAuthenticationProvider>(),
                        baseUrl);

                    var user = await client.Me.GetAsync();

                    if (user is not null)
                    {
                        userIdentity.AddClaim(new Claim("mobilephone",
                            user.MobilePhone ?? "(000) 000-0000"));
                        userIdentity.AddClaim(new Claim("officelocation",
                            user.OfficeLocation ?? "Not set"));
                    }

                    var memberOf = client.Users[account?.Oid].MemberOf;

                    var graphDirectoryRoles = await
memberOf.GraphDirectoryRole.GetAsync();

                    if (graphDirectoryRoles?.Value is not null)
```

```
                    {
                        foreach (var entry in graphDirectoryRoles.Value)
                        {
                            if (entry.RoleTemplateId is not null)
                            {
                                userIdentity.AddClaim(
                                    new Claim("directoryRole",
entry.RoleTemplateId));
                            }
                        }
                    }

                    var graphAdministrativeUnits = await
memberOf.GraphAdministrativeUnit.GetAsync();

                    if (graphAdministrativeUnits?.Value is not null)
                    {
                        foreach (var entry in
graphAdministrativeUnits.Value)
                        {
                            if (entry.Id is not null)
                            {
                                userIdentity.AddClaim(
                                    new Claim("administrativeUnit",
entry.Id));
                            }
                        }
                    }

                    var graphGroups = await memberOf.GraphGroup.GetAsync();

                    if (graphGroups?.Value is not null)
                    {
                        foreach (var entry in graphGroups.Value)
                        {
                            if (entry.Id is not null)
                            {
                                userIdentity.AddClaim(
                                    new Claim("directoryGroup", entry.Id));
                            }
                        }
                    }
                }
                catch (AccessTokenNotAvailableException exception)
                {
                    exception.Redirect();
                }
            }
        }

        return initialUser;
    }
}
```

The preceding code:

- Doesn't include transitive memberships. If the app requires direct and transitive group membership claims, replace the `MemberOf` property (`IUserMemberOfCollectionWithReferencesRequestBuilder`) with `TransitiveMemberOf` (`IUserTransitiveMemberOfCollectionWithReferencesRequestBuilder`).
- Sets GUID values in `directoryRole` claims are ME-ID Administrator Role *Template IDs* (`Microsoft.Graph.Models.DirectoryRole.RoleTemplateId`). Template IDs are stable identifiers for creating user authorization policies in apps, which is covered later in this article. Don't use `entry.Id` for directory role claim values, as they aren't stable across tenants.

Next, configure the MSAL authentication to use the custom user account factory.

Confirm that the `Program` file uses the Microsoft.AspNetCore.Components.WebAssembly.Authentication namespace:

C#

```
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
```

Update the AddMsalAuthentication call to the following. Note that the Blazor framework's RemoteUserAccount is replaced by the app's `CustomUserAccount` for the MSAL authentication and account claims principal factory:

C#

```
builder.Services.AddMsalAuthentication<RemoteAuthenticationState,
    CustomUserAccount>(options =>
    {
        builder.Configuration.Bind("AzureAd",
            options.ProviderOptions.Authentication);
        options.UserOptions.RoleClaim = "role";
    })
    .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
CustomUserAccount,
        CustomAccountFactory>();
```

Confirm the presence of the *Graph SDK* code in the `Program` file described by the Use Graph API with ASP.NET Core Blazor WebAssembly article:

C#

```
var baseUrl =
    string.Join("/",
```

```
        builder.Configuration.GetSection("MicrosoftGraph")["BaseUrl"] ??
            "https://graph.microsoft.com",
        builder.Configuration.GetSection("MicrosoftGraph")["Version"] ??
            "v1.0");
var scopes = builder.Configuration.GetSection("MicrosoftGraph:Scopes")
    .Get<List<string>>() ?? [ "user.read" ];

builder.Services.AddGraphClient(baseUrl, scopes);
```

> **ⓘ Important**
>
> Confirm in the app's registration in the Azure portal that the following permissions are granted:
>
> - `User.Read`
> - `RoleManagement.Read.Directory` (Requires admin consent)
> - `AdministrativeUnit.Read.All` (Requires admin consent)

Confirm that the `wwwroot/appsettings.json` configuration is correct per the *Graph SDK* guidance.

`wwwroot/appsettings.json`:

JSON

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/{TENANT ID}",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": true
  },
  "MicrosoftGraph": {
    "BaseUrl": "https://graph.microsoft.com",
    "Version": "v1.0",
    "Scopes": [
      "User.Read",
      "RoleManagement.Read.Directory",
      "AdministrativeUnit.Read.All"
    ]
  }
}
```

Provide values for the following placeholders from the app's ME-ID registration in the Azure portal:

- `{TENANT ID}`: The Directory (Tenant) Id GUID value.

- `{CLIENT ID}`: The Application (Client) Id GUID value.

Authorization configuration

Create a policy for each App Role (by role name), ME-ID built-in Administrator Role (by Role Template Id/GUID), or security group (by Object Id/GUID) in the `Program` file. The following example creates a policy for the ME-ID built-in *Billing Administrator* role:

C#

```
builder.Services.AddAuthorizationCore(options =>
{
    options.AddPolicy("BillingAdministrator", policy =>
        policy.RequireClaim("directoryRole",
            "b0f54661-2d74-4c50-afa3-1ec803f12efe"));
});
```

For the complete list of IDs (GUIDs) for ME-ID Administrator Roles, see Role template IDs in the ME-ID documentation. For an Azure security or O365 group ID (GUID), see the **Object Id** for the group in the Azure portal **Groups** pane of the app's registration. For more information on authorization policies, see Policy-based authorization in ASP.NET Core.

In the following examples, the app uses the preceding policy to authorize the user.

The AuthorizeView component works with the policy:

razor

```
<AuthorizeView Policy="BillingAdministrator">
    <Authorized>
        <p>
            The user is in the 'Billing Administrator' ME-ID Administrator
Role
            and can see this content.
        </p>
    </Authorized>
    <NotAuthorized>
        <p>
            The user is NOT in the 'Billing Administrator' role and sees
this
            content.
        </p>
    </NotAuthorized>
</AuthorizeView>
```

Access to an entire component can be based on the policy using an [Authorize] attribute directive (AuthorizeAttribute):

razor

```
@page "/"
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize(Policy = "BillingAdministrator")]
```

If the user isn't authorized, they're redirected to the ME-ID sign-in page.

A policy check can also be performed in code with procedural logic.

`CheckPolicy.razor`:

razor

```
@page "/checkpolicy"
@using Microsoft.AspNetCore.Authorization
@inject IAuthorizationService AuthorizationService

<h1>Check Policy</h1>

<p>This component checks a policy in code.</p>

<button @onclick="CheckPolicy">Check 'BillingAdministrator' policy</button>

<p>Policy Message: @policyMessage</p>

@code {
    private string policyMessage = "Check hasn't been made yet.";

    [CascadingParameter]
    private Task<AuthenticationState> authenticationStateTask { get; set; }

    private async Task CheckPolicy()
    {
        var user = (await authenticationStateTask).User;

        if ((await AuthorizationService.AuthorizeAsync(user,
            "BillingAdministrator")).Succeeded)
        {
            policyMessage = "Yes! The 'BillingAdministrator' policy is
met.";
        }
        else
        {
            policyMessage = "No! 'BillingAdministrator' policy is NOT met.";
        }
    }
}
```

Using the preceding approaches, you can also create policy-based access for security groups, where the GUID used for the policy matches the

App Roles

To configure the app in the Azure portal to provide App Roles membership claims, see Add app roles to your application and receive them in the token in the ME-ID documentation.

The following example assumes that the app is configured with two roles, and the roles are assigned to a test user:

- `Admin`
- `Developer`

Although you can't assign roles to groups without an ME-ID Premium account, you can assign roles to users and receive role claims for users with a standard Azure account. The guidance in this section doesn't require an ME-ID Premium account.

Take either of the following approaches add app roles in ME-ID:

- When working with the ***default directory***, follow the guidance in Add app roles to your application and receive them in the token to create ME-ID roles.
- If you ***aren't working with the default directory***, edit the app's manifest in the Azure portal to establish the app's roles manually in the `appRoles` entry of the manifest file. The following is an example `appRoles` entry that creates `Admin` and `Developer` roles. These example roles are used later at the component level to implement access restrictions:

  > **ⓘ Important**
  >
  > The following approach is only recommended for apps that aren't registered in the Azure account's default directory. For apps registered in the default directory, see the preceding bullet of this list.

  JSON

  ```
  "appRoles": [
    {
      "allowedMemberTypes": [
        "User"
      ],
  ```

```
      "description": "Administrators manage developers.",
      "displayName": "Admin",
      "id": "{ADMIN GUID}",
      "isEnabled": true,
      "lang": null,
      "origin": "Application",
      "value": "Admin"
    },
    {
      "allowedMemberTypes": [
        "User"
      ],
      "description": "Developers write code.",
      "displayName": "Developer",
      "id": "{DEVELOPER GUID}",
      "isEnabled": true,
      "lang": null,
      "origin": "Application",
      "value": "Developer"
    }
  ],
```

For the `{ADMIN GUID}` and `{DEVELOPER GUID}` placeholders in the preceding example, you can generate GUIDs with an online GUID generator (Google search result for "guid generator").

To assign a role to a user (or group if you have a Premium tier Azure account):

1. Navigate to **Enterprise applications** in the ME-ID area of the Azure portal.
2. Select the app. Select **Manage** > **Users and groups** from the sidebar.
3. Select the checkbox for one or more user accounts.
4. From the menu above the list of users, select **Edit assignment**.
5. For the **Select a role** entry, select **None selected**.
6. Choose a role from the list and use the **Select** button to select it.
7. Use the **Assign** button at the bottom of the screen to assign the role.

Multiple roles are assigned in the Azure portal by ***re-adding a user*** for each additional role assignment. Use the **Add user/group** button at the top of the list of users to re-add a user. Use the preceding steps to assign another role to the user. You can repeat this process as many times as needed to add additional roles to a user (or group).

The `CustomAccountFactory` shown in the Custom user account section is set up to act on a `role` claim with a JSON array value. Add and register the `CustomAccountFactory` in the app as shown in the Custom user account section. There's no need to provide code to remove the original `role` claim because it's automatically removed by the framework.

In the `Program` file, add or confirm the claim named "`role`" as the role claim for ClaimsPrincipal.IsInRole checks:

```
C#

builder.Services.AddMsalAuthentication(options =>
{
    ...

    options.UserOptions.RoleClaim = "role";
});
```

> **Note**
>
> If you prefer to use the `directoryRoles` claim (ME-ID Administrator Roles), assign "`directoryRoles`" to the RemoteAuthenticationUserOptions.RoleClaim.

After you've completed the preceding steps to create and assign roles to users (or groups if you have a Premium tier Azure account) and implemented the `CustomAccountFactory` with the Graph SDK, as explained earlier in this article and in Use Graph API with ASP.NET Core Blazor WebAssembly, you should see an `role` claim for each assigned role that a signed-in user is assigned (or roles assigned to groups that they are members of). Run the app with a test user to confirm the claims are present as expected. When testing with the Graph SDK locally, we recommend using a new in-private/incognito browser session for each test to prevent lingering cookies from interfering with tests. For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID.

Component authorization approaches are functional at this point. Any of the authorization mechanisms in components of the app can use the `Admin` role to authorize the user:

- AuthorizeView component

  ```
  razor

  <AuthorizeView Roles="Admin">
  ```

- [Authorize] attribute directive (AuthorizeAttribute)

  ```
  razor
  ```

```
@attribute [Authorize(Roles = "Admin")]
```

- Procedural logic

```
C#

var authState = await
AuthenticationStateProvider.GetAuthenticationStateAsync();
var user = authState.User;

if (user.IsInRole("Admin")) { ... }
```

Multiple role tests are supported:

- Require that the user be in **either** the `Admin` **or** `Developer` role with the `AuthorizeView` component:

```
razor

<AuthorizeView Roles="Admin, Developer">
    ...
</AuthorizeView>
```

- Require that the user be in **both** the `Admin` **and** `Developer` roles with the `AuthorizeView` component:

```
razor

<AuthorizeView Roles="Admin">
    <AuthorizeView Roles="Developer" Context="innerContext">
        ...
    </AuthorizeView>
</AuthorizeView>
```

  For more information on the `Context` for the inner AuthorizeView, see ASP.NET Core Blazor authentication and authorization.

- Require that the user be in **either** the `Admin` **or** `Developer` role with the `[Authorize]` attribute:

```
razor

@attribute [Authorize(Roles = "Admin, Developer")]
```

- Require that the user be in **both** the `Admin` **and** `Developer` roles with the `[Authorize]` attribute:

```razor
@attribute [Authorize(Roles = "Admin")]
@attribute [Authorize(Roles = "Developer")]
```

- Require that the user be in **either** the `Admin` **or** `Developer` role with procedural code:

```razor
@code {
    private async Task DoSomething()
    {
        var authState = await AuthenticationStateProvider
            .GetAuthenticationStateAsync();
        var user = authState.User;

        if (user.IsInRole("Admin") || user.IsInRole("Developer"))
        {
            ...
        }
        else
        {
            ...
        }
    }
}
```

- Require that the user be in **both** the `Admin` **and** `Developer` roles with procedural code by changing the conditional OR (||) to a conditional AND (&&) in the preceding example:

```C#
if (user.IsInRole("Admin") && user.IsInRole("Developer"))
```

Multiple role tests are supported:

- Require that the user be in **either** the `Admin` **or** `Developer` role with the `[Authorize]` attribute:

```C#
```

```
[Authorize(Roles = "Admin, Developer")]
```

- Require that the user be in **both** the `Admin` **and** `Developer` roles with the `[Authorize]` attribute:

```
C#

[Authorize(Roles = "Admin")]
[Authorize(Roles = "Developer")]
```

- Require that the user be in **either** the `Admin` **or** `Developer` role with procedural code:

```
C#

static readonly string[] scopeRequiredByApi = new string[] {
"API.Access" };

...

[HttpGet]
public IEnumerable<ReturnType> Get()
{
    HttpContext.VerifyUserHasAnyAcceptedScope(scopeRequiredByApi);

    if (User.IsInRole("Admin") || User.IsInRole("Developer"))
    {
        ...
    }
    else
    {
        ...
    }

    return ...
}
```

- Require that the user be in **both** the `Admin` **and** `Developer` roles with procedural code by changing the conditional OR (||) to a conditional AND (&&) in the preceding example:

```
C#

if (User.IsInRole("Admin") && User.IsInRole("Developer"))
```

Because .NET string comparisons are case-sensitive, matching role names is also case-sensitive. For example, `Admin` (uppercase `A`) is not treated as the same role as `admin` (lowercase `a`).

Pascal case is typically used for role names (for example, `BillingAdministrator`), but the use of Pascal case isn't a strict requirement. Different casing schemes, such as camel case, kebab case, and snake case, are permitted. Using spaces in role names is also unusual but permitted. For example, `billing administrator` is an unusual role name format in .NET apps but valid.

Use Graph API with ASP.NET Core Blazor WebAssembly

Article • 11/06/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to use Microsoft Graph in Blazor WebAssembly apps, which enables apps to access Microsoft Cloud resources.

Two approaches are covered:

- **Graph SDK**: The Microsoft Graph SDK simplifies building high-quality, efficient, and resilient apps that access Microsoft Graph. Select the **Graph SDK** button at the top of this article to adopt this approach.
- **Named HttpClient with Graph API**: A named HttpClient can issue Microsoft Graph API requests directly to Microsoft Graph. Select the **Named HttpClient with Graph API** button at the top of this article to adopt this approach.

The guidance in this article isn't meant to replace the Microsoft Graph documentation and Azure security guidance in other Microsoft documentation sets. Assess the security guidance in the Additional resources section of this article before implementing Microsoft Graph in a production environment. Follow Microsoft's best practices to limit the vulnerabilities of your apps.

Additional approaches for working with Microsoft Graph and Blazor WebAssembly are provided by the following Microsoft Graph and Azure samples:

- Microsoft Graph sample Blazor WebAssembly app: The sample adopts a factory-based approach with the Microsoft Graph SDK to obtain Office 365 data. The sample uses a default HttpClient to make Graph client requests. If you need to use the default HttpClient with the base address of the app (`BaseAddress = new Uri(builder.HostEnvironment.BaseAddress)`) for other purposes, for example to load data from the web root of the app, consider refactoring the Graph client factory to use a named HttpClient dedicated to Graph requests.

- ASP.NET Core 8.0 Blazor WebAssembly | standalone app | user sign-in, protected web API access (Microsoft Graph) | Microsoft identity platform: The sample is a Progressive Web Application (PWA) that uses an authorization message handler and HttpClient to obtain Graph data. As with the preceding sample, this sample also uses a default HttpClient to make Graph client requests. Instead of using the Microsoft Graph SDK, the sample retrieves user account data as JSON via a Microsoft Graph API request in a component. This is a similar technique to the **Named HttpClient with Graph API** approach in this article (use the button at the top of this article to see the guidance), except that this article's guidance uses a named HttpClient dedicated to Graph requests.

To provide feedback on either of the preceding two samples, open an issue on the sample's GitHub repository. If you're opening an issue for the Azure sample, provide a link to the sample in your opening comment because the Azure sample repository (`Azure-Samples`) contains many samples. Describe the problem in detail and include sample code as needed. Place a minimal app into GitHub that reproduces the problem or error. Be sure to remove Azure account configuration data from the sample before you commit it to the public repository.

To provide feedback or seek assistance with this article or ASP.NET Core, see ASP.NET Core Blazor fundamentals.

> **Important**
>
> The scenarios described in this article apply to using Microsoft Entra (ME-ID) as the identity provider, not AAD B2C. Using Microsoft Graph with a client-side Blazor WebAssembly app and the AAD B2C identity provider isn't supported at this time because the app would require a client secret, which can't be secured in the client-side Blazor app. For an AAD B2C standalone Blazor WebAssembly app use Graph API, create a backend server (web) API to access Graph API on behalf of users. The client-side app authenticates and authorizes users to call the web API to securely access Microsoft Graph and return data to the client-side Blazor app from your server-based web API. The client secret is safely maintained in the server-based web API, not in the Blazor app on the client. **Never store a client secret in a client-side Blazor app.**

The examples in this article take advantage of new .NET/C# features. When using the examples with .NET 7 or earlier, minor modifications are required. However, the text and code examples that pertain to interacting with Microsoft Graph are the same for all versions of ASP.NET Core.

The following guidance applies to Microsoft Graph v4. If you're upgrading an app from SDK v4 to v5, see the Microsoft Graph .NET SDK v5 changelog and upgrade guide.

The Microsoft Graph SDK for use in Blazor apps is called the *Microsoft Graph .NET Client Library*.

The Graph SDK examples require the following package references in the standalone Blazor WebAssembly app. The first two packages are already referenced if the app has been enabled for MSAL authentication, for example when creating the app by following the guidance in Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID.

- Microsoft.AspNetCore.Components.WebAssembly.Authentication
- Microsoft.Authentication.WebAssembly.Msal
- Microsoft.Extensions.Http
- Microsoft.Graph

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

In the Azure portal, grant delegated permissions (scopes)† for Microsoft Graph data that the app should be able to access on behalf of a user. For the example in this article, the app's registration should include delegated permission to read user data (`Microsoft.Graph` > `User.Read` scope in **API permissions**, Type: Delegated). The `User.Read` scope allows users to sign in to the app and allows the app to read the profile and company information of signed-in users. For more information, see Overview of permissions and consent in the Microsoft identity platform and Overview of Microsoft Graph permissions.

†*Permissions* and *scopes* mean the same thing and are used interchangeably in security documentation and the Azure portal. Unless the text is referring to the Azure portal, this article uses *scope/scopes* when referring to Graph permissions.

Scopes are case insensitive, so `User.Read` is the same as `user.read`. Feel free to use either format, but we recommend a consistent choice across application code.

After adding the Microsoft Graph API scopes to the app's registration in the Azure portal, add the following app settings configuration to the `wwwroot/appsettings.json` file in the app, which includes the Graph base URL with the Microsoft Graph version and

scopes. In the following example, the `User.Read` scope is specified for the examples in later sections of this article. Scopes aren't case sensitive.

JSON

```
"MicrosoftGraph": {
  "BaseUrl": "https://graph.microsoft.com",
  "Version": "{VERSION}",
  "Scopes": [
    "user.read"
  ]
}
```

In the preceding example, the `{VERSION}` placeholder is the version of the Microsoft Graph API (for example: `v1.0`).

The following is an example of a complete `wwwroot/appsettings.json` configuration file for an app that uses ME-ID as its identity provider, where reading user data (`user.read` scope) is specified for Microsoft Graph:

JSON

```
{
  "AzureAd": {
    "Authority": "https://login.microsoftonline.com/{TENANT ID}",
    "ClientId": "{CLIENT ID}",
    "ValidateAuthority": true
  },
  "MicrosoftGraph": {
    "BaseUrl": "https://graph.microsoft.com",
    "Version": "v1.0",
    "Scopes": [
      "user.read"
    ]
  }
}
```

In the preceding example, the `{TENANT ID}` placeholder is the Directory (tenant) ID, and the `{CLIENT ID}` placeholder is the Application (client) ID. For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID.

Add the following `GraphClientExtensions` class to the standalone app. The scopes are provided to the Scopes property of the AccessTokenRequestOptions in the `AuthenticateRequestAsync` method. The IHttpProvider.OverallTimeout is extended from the default value of 100 seconds to 300 seconds to give the HttpClient more time to receive a response from Microsoft Graph.

When an access token isn't obtained, the following code doesn't set a Bearer authorization header for Graph requests.

`GraphClientExtensions.cs`:

C#

```
using System.Net.Http.Headers;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.Authentication.WebAssembly.Msal.Models;
using Microsoft.Graph;

namespace BlazorSample;

internal static class GraphClientExtensions
{
    public static IServiceCollection AddGraphClient(
        this IServiceCollection services, string? baseUrl, List<string>?
scopes)
    {
        if (string.IsNullOrEmpty(baseUrl) || scopes?.Count == 0)
        {
            return services;
        }

        services.Configure<RemoteAuthenticationOptions<MsalProviderOptions>>
(
            options =>
            {
                scopes?.ForEach((scope) =>
                {

options.ProviderOptions.DefaultAccessTokenScopes.Add(scope);
                });
            });

        services.AddScoped<IAuthenticationProvider,
GraphAuthenticationProvider>();

        services.AddScoped<IHttpProvider, HttpClientHttpProvider>(sp =>
            new HttpClientHttpProvider(new HttpClient()));

        services.AddScoped(sp =>
        {
            return new GraphServiceClient(
                baseUrl,
                sp.GetRequiredService<IAuthenticationProvider>(),
                sp.GetRequiredService<IHttpProvider>());
        });

        return services;
    }
```

```
    private class GraphAuthenticationProvider(IAccessTokenProvider
tokenProvider,
        IConfiguration config) : IAuthenticationProvider
    {
        private readonly IConfiguration config = config;

        public IAccessTokenProvider TokenProvider { get; } = tokenProvider;

        public async Task AuthenticateRequestAsync(HttpRequestMessage
request)
        {
            var result = await TokenProvider.RequestAccessToken(
                new AccessTokenRequestOptions()
                {
                    Scopes =
config.GetSection("MicrosoftGraph:Scopes").Get<string[]>()
                });

            if (result.TryGetToken(out var token))
            {
                request.Headers.Authorization ??= new
AuthenticationHeaderValue(
                    "Bearer", token.Value);
            }
        }
    }

    private class HttpClientHttpProvider(HttpClient client) : IHttpProvider
    {
        private readonly HttpClient client = client;

        public ISerializer Serializer { get; } = new Serializer();

        public TimeSpan OverallTimeout { get; set; } =
TimeSpan.FromSeconds(300);

        public Task<HttpResponseMessage> SendAsync(HttpRequestMessage
request)
        {
            return client.SendAsync(request);
        }

        public Task<HttpResponseMessage> SendAsync(HttpRequestMessage
request,
            HttpCompletionOption completionOption,
            CancellationToken cancellationToken)
        {
            return client.SendAsync(request, completionOption,
cancellationToken);
        }

        public void Dispose()
        {
        }
```

```
    }
}
```

> **Important**
>
> See the DefaultAccessTokenScopes versus AdditionalScopesToConsent section for an explanation on why the preceding code uses DefaultAccessTokenScopes to add the scopes rather than AdditionalScopesToConsent.

In the `Program` file, add the Graph client services and configuration with the `AddGraphClient` extension method:

C#

```
var baseUrl = string.Join("/",
    builder.Configuration.GetSection("MicrosoftGraph")["BaseUrl"] ??
        "https://graph.microsoft.com",
    builder.Configuration.GetSection("MicrosoftGraph")["Version"] ??
        "v1.0");
var scopes = builder.Configuration.GetSection("MicrosoftGraph:Scopes")
    .Get<List<string>>() ?? [ "user.read" ];

builder.Services.AddGraphClient(baseUrl, scopes);
```

Call Graph API from a component using the Graph SDK

The following `UserData` component uses an injected `GraphServiceClient` to obtain the user's ME-ID profile data and display their mobile phone number. For any test user that you create in ME-ID, make sure that you give the user's ME-ID profile a mobile phone number in the Azure portal.

`UserData.razor`:

razor

```
@page "/user-data"
@using Microsoft.AspNetCore.Authorization
@using Microsoft.Graph
@attribute [Authorize]
@inject GraphServiceClient Client

<PageTitle>User Data</PageTitle>
```

```razor
<h1>Microsoft Graph User Data</h1>

@if (!string.IsNullOrEmpty(user?.MobilePhone))
{
    <p>Mobile Phone: @user.MobilePhone</p>
}

@code {
    private Microsoft.Graph.User? user;

    protected override async Task OnInitializedAsync()
    {
        var request = Client.Me.Request();
        user = await request.GetAsync();
    }
}
```

Add a link to the component's page in the `NavMenu` component (`Layout/NavMenu.razor`):

razor

```razor
<div class="nav-item px-3">
    <NavLink class="nav-link" href="user-data">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
User Data
    </NavLink>
</div>
```

> **Tip**
>
> To add users to an app, see the **Assign users to an app registration with or without app roles** section.

When testing with the Graph SDK locally, we recommend using a new InPrivate/incognito browser session for each test to prevent lingering cookies from interfering with tests. For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID.

Customize user claims using the Graph SDK

In the following example, the app creates mobile phone number and office location claims for a user from their ME-ID user profile's data. The app must have the `User.Read` Graph API scope configured in ME-ID. Any test users for this scenario must have a mobile phone number and office location in their ME-ID profile, which can be added via the Azure portal.

In the following custom user account factory:

- An ILogger (`logger`) is included for convenience in case you wish to log information or errors in the `CreateUserAsync` method.
- In the event that an AccessTokenNotAvailableException is thrown, the user is redirected to the identity provider to sign into their account. Additional or different actions can be taken when requesting an access token fails. For example, the app can log the AccessTokenNotAvailableException and create a support ticket for further investigation.
- The framework's RemoteUserAccount represents the user's account. If the app requires a custom user account class that extends RemoteUserAccount, swap your custom user account class for RemoteUserAccount in the following code.

`CustomAccountFactory.cs`:

C#

```
using System.Security.Claims;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using Microsoft.AspNetCore.Components.WebAssembly.Authentication.Internal;
using Microsoft.Graph;

public class CustomAccountFactory(IAccessTokenProviderAccessor accessor,
        IServiceProvider serviceProvider, ILogger<CustomAccountFactory>
logger)
    : AccountClaimsPrincipalFactory<RemoteUserAccount>(accessor)
{
    private readonly ILogger<CustomAccountFactory> logger = logger;
    private readonly IServiceProvider serviceProvider = serviceProvider;

    public override async ValueTask<ClaimsPrincipal> CreateUserAsync(
        RemoteUserAccount account,
        RemoteAuthenticationUserOptions options)
    {
        var initialUser = await base.CreateUserAsync(account, options);

        if (initialUser.Identity is not null &&
            initialUser.Identity.IsAuthenticated)
        {
            var userIdentity = initialUser.Identity as ClaimsIdentity;

            if (userIdentity is not null)
            {
                try
                {
                    var client = ActivatorUtilities
                        .CreateInstance<GraphServiceClient>
(serviceProvider);
                    var request = client.Me.Request();
                    var user = await request.GetAsync();
```

```
                    if (user is not null)
                    {
                        userIdentity.AddClaim(new Claim("mobilephone",
                            user.MobilePhone ?? "(000) 000-0000"));
                        userIdentity.AddClaim(new Claim("officelocation",
                            user.OfficeLocation ?? "Not set"));
                    }
                }
                catch (AccessTokenNotAvailableException exception)
                {
                    exception.Redirect();
                }
            }
        }

        return initialUser;
    }
}
```

Configure the MSAL authentication to use the custom user account factory.

Confirm that the `Program` file uses the Microsoft.AspNetCore.Components.WebAssembly.Authentication namespace:

C#

```
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
```

The example in this section builds on the approach of reading the base URL with version and scopes from app configuration via the `MicrosoftGraph` section in `wwwroot/appsettings.json` file. The following lines should already be present in the `Program` file from following the guidance earlier in this article:

C#

```
var baseUrl = string.Join("/",
    builder.Configuration.GetSection("MicrosoftGraph")["BaseUrl"] ??
        "https://graph.microsoft.com",
    builder.Configuration.GetSection("MicrosoftGraph")["Version"] ??
        "v1.0");
var scopes = builder.Configuration.GetSection("MicrosoftGraph:Scopes")
    .Get<List<string>>() ?? [ "user.read" ];

builder.Services.AddGraphClient(baseUrl, scopes);
```

In the `Program` file, find the call to the AddMsalAuthentication extension method. Update the code to the following, which includes a call to

AddAccountClaimsPrincipalFactory that adds an account claims principal factory with the `CustomAccountFactory`.

If the app uses a custom user account class that extends RemoteUserAccount, swap the custom user account class for RemoteUserAccount in the following code.

C#

```
builder.Services.AddMsalAuthentication<RemoteAuthenticationState,
    RemoteUserAccount>(options =>
    {
        builder.Configuration.Bind("AzureAd",
            options.ProviderOptions.Authentication);
    })
    .AddAccountClaimsPrincipalFactory<RemoteAuthenticationState,
RemoteUserAccount,
        CustomAccountFactory>();
```

You can use the following `UserClaims` component to study the user's claims after the user authenticates with ME-ID:

`UserClaims.razor`:

razor

```
@page "/user-claims"
@using System.Security.Claims
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize]
@inject AuthenticationStateProvider AuthenticationStateProvider

<h1>User Claims</h1>

@if (claims.Any())
{
    <ul>
        @foreach (var claim in claims)
        {
            <li>@claim.Type: @claim.Value</li>
        }
    </ul>
}
else
{
    <p>No claims found.</p>
}

@code {
    private IEnumerable<Claim> claims = Enumerable.Empty<Claim>();

    protected override async Task OnInitializedAsync()
```

```
    {
        var authState = await AuthenticationStateProvider
            .GetAuthenticationStateAsync();
        var user = authState.User;

        claims = user.Claims;
    }
}
```

Add a link to the component's page in the `NavMenu` component (`Layout/NavMenu.razor`):

razor

```
<div class="nav-item px-3">
    <NavLink class="nav-link" href="user-claims">
        <span class="bi bi-list-nested-nav-menu" aria-hidden="true"></span>
User Claims
    </NavLink>
</div>
```

When testing with the Graph SDK locally, we recommend using a new InPrivate/incognito browser session for each test to prevent lingering cookies from interfering with tests. For more information, see Secure an ASP.NET Core Blazor WebAssembly standalone app with Microsoft Entra ID.

Assign users to an app registration with or without app roles

You can add users to an app registration and assign roles to users with the following steps in the Azure portal.

To add a user, select **Users** from the ME-ID area of the Azure portal:

1. Select **New user** > **Create new user**.
2. Use the **Create user** template.
3. Supply the user's information in the **Identity** area.
4. You can generate an initial password or assign an initial password that the user changes when they sign in for the first time. If you use the password generated by the portal, make a note of it now.
5. Select **Create** to create the user. When **Create new user** interface closes, select **Refresh** to update the user list and show the new user.
6. For the examples in this article, assign a mobile phone number to the new user by selecting their name from the users list, selecting **Properties**, and editing the contact information to provide a mobile phone number.

To assign users to the app *without app roles*:

1. In the ME-ID area of the Azure portal, open **Enterprise applications**.
2. Select the app from the list.
3. Select **Users and groups**.
4. Select **Add user/group**.
5. Select a user.
6. Select the **Assign** button.

To assign users to the app *with app roles*:

1. Add roles to the app's registration in the Azure portal following the guidance in ASP.NET Core Blazor WebAssembly with Microsoft Entra ID groups and roles.
2. In the ME-ID area of the Azure portal, open **Enterprise applications**.
3. Select the app from the list.
4. Select **Users and groups**.
5. Select **Add user/group**.
6. Select a user and select their role for accessing the app. Multiple roles are assigned to a user by repeating the process of adding the user to the app until all of the roles for a user are assigned. Users with multiple roles are listed once for each assigned role in the **Users and groups** list of users for the app.
7. Select the **Assign** button.

`DefaultAccessTokenScopes` versus `AdditionalScopesToConsent`

The examples in this article provision Graph API scopes with DefaultAccessTokenScopes, not AdditionalScopesToConsent.

AdditionalScopesToConsent isn't used because it's unable to provision Graph API scopes for users when they sign in to the app for the first time with MSAL via the Azure consent UI. When the user attempts to access Graph API for the first time with the Graph SDK, they're confronted with an exception:

> Microsoft.Graph.Models.ODataErrors.ODataError: Access token is empty.

After a user provisions Graph API scopes provided via DefaultAccessTokenScopes, the app can use AdditionalScopesToConsent for a subsequent user sign in. However, changing app code makes no sense for a production app that requires the periodic addition of new users with delegated Graph scopes or adding new delegated Graph API scopes to the app.

The preceding discussion of how to provision scopes for Graph API access when the user first signs into the app only applies to:

- Apps that adopt the Graph SDK.
- Apps that use a named HttpClient for Graph API access that asks users to consent to Graph scopes on their first sign in to the app.

When using a named HttpClient that doesn't ask users to consent to Graph scopes on their first sign in, users are redirected to the Azure consent UI for Graph API scopes consent *when they first request access to Graph API* via the DelegatingHandler of the preconfigured, named HttpClient. When Graph scopes aren't consented initially with the named HttpClient approach, neither DefaultAccessTokenScopes nor AdditionalScopesToConsent are called by the app. For more information, see the named HttpClient coverage in this article.

Additional resources

General guidance

- Microsoft Graph documentation
- Microsoft Graph sample Blazor WebAssembly app : This sample demonstrates how to use the Microsoft Graph .NET SDK to access data in Office 365 from Blazor WebAssembly apps.
- Build .NET apps with Microsoft Graph tutorial and Microsoft Graph sample ASP.NET Core app : Although these resources don't directly apply to calling Graph from *client-side* Blazor WebAssembly apps, the ME-ID app configuration and Microsoft Graph coding practices in the linked resources are relevant for standalone Blazor WebAssembly apps and should be consulted for general best practices.

Security guidance

Secure an ASP.NET Core Blazor Web App with Microsoft Entra ID

Article • 10/09/2024

This article describes how to secure a Blazor Web App with Microsoft identity platform/Microsoft Identity Web packages for Microsoft Entra ID using a sample app.

The following specification is covered:

- The Blazor Web App uses the Auto render mode with global interactivity (InteractiveAuto).
- The server project calls `AddAuthenticationStateSerialization` to add a server-side authentication state provider that uses PersistentComponentState to flow the authentication state to the client. The client calls `AddAuthenticationStateDeserialization` to deserialize and use the authentication state passed by the server. The authentication state is fixed for the lifetime of the WebAssembly application.
- The app uses Microsoft Entra ID, based on Microsoft Identity Web packages.
- Automatic non-interactive token refresh is managed by the framework.
- The app uses server-side and client-side service abstractions to display generated weather data:
  - When rendering the `Weather` component on the server to display weather data, the component uses the `ServerWeatherForecaster` on the server to directly obtain weather data (not via a web API call).
  - When the `Weather` component is rendered on the client, the component uses the `ClientWeatherForecaster` service implementation, which uses a preconfigured HttpClient (in the client project's `Program` file) to make a web API call to the server project's Minimal API (`/weather-forecast`) for weather data. The Minimal API endpoint obtains the weather data from the `ServerWeatherForecaster` class and returns it to the client for rendering by the component.

Sample app

The sample app consists of two projects:

- `BlazorWebAppEntra`: Server-side project of the Blazor Web App, containing an example Minimal API endpoint for weather data.
- `BlazorWebAppEntra.Client`: Client-side project of the Blazor Web App.

Access sample apps through the latest version folder from the repository's root with the following link. The projects are in the `BlazorWebAppEntra` folder for .NET 9 or later.

View or download sample code (how to download)

Server-side Blazor Web App project (`BlazorWebAppEntra`)

The `BlazorWebAppEntra` project is the server-side project of the Blazor Web App.

The `BlazorWebAppEntra.http` file can be used for testing the weather data request. Note that the `BlazorWebAppEntra` project must be running to test the endpoint, and the endpoint is hardcoded into the file. For more information, see Use .http files in Visual Studio 2022.

Client-side Blazor Web App project (`BlazorWebAppEntra.Client`)

The `BlazorWebAppEntra.Client` project is the client-side project of the Blazor Web App.

If the user needs to log in or out during client-side rendering, a full page reload is initiated.

Configuration

This section explains how to configure the sample app.

AddMicrosoftIdentityWebApp from Microsoft Identity Web (Microsoft.Identity.Web NuGet package, API documentation) is configured by the `AzureAd` section of the server project's `appsettings.json` file.

In the app's registration in the Entra or Azure portal, use a **Web** platform configuration with a **Redirect URI** of `https://localhost/signin-oidc` (a port isn't required). Confirm that **ID tokens** and access tokens under **Implicit grant and hybrid flows** are **not** selected. The OpenID Connect handler automatically requests the appropriate tokens using the code returned from the authorization endpoint.

Establish the client secret

Use the Secret Manager tool to store the server app's client secret under the configuration key `AzureAd:ClientSecret`.

Create a client secret in the app's Entra ID registration in the Entra or Azure portal (**Manage** > **Certificates & secrets** > **New client secret**). Use the **Value** of the new secret in the following guidance.

Execute the following command in a command shell from the server project's directory, such as the Developer PowerShell command shell in Visual Studio. The `{SECRET}` placeholder is the client secret obtained from the app's registration:

.NET CLI

```
dotnet user-secrets set "AzureAd:ClientSecret" "{SECRET}"
```

If using Visual Studio, you can confirm the secret is set by right-clicking the server project in **Solution Explorer** and selecting **Manage User Secrets**.

Configure the app

In the server project's app settings file (`appsettings.json`), provide the app's `AzureAd` section configuration. Obtain the application (client) ID, tenant (publisher) domain, and directory (tenant) ID from the app's registration in the Entra or Azure portal:

JSON

```
"AzureAd": {
  "CallbackPath": "/signin-oidc",
  "ClientId": "{CLIENT ID}",
  "Domain": "{DOMAIN}",
  "Instance": "https://login.microsoftonline.com/",
  "ResponseType": "code",
  "TenantId": "{TENANT ID}"
},
```

Placeholders in the preceding example:

- `{CLIENT ID}`: The application (client) ID.
- `{DOMAIN}`: The tenant (publisher) domain.
- `{TENANT ID}`: The directory (tenant) ID.

Example:

JSON

```
"AzureAd": {
  "CallbackPath": "/signin-oidc",
  "ClientId": "00001111-aaaa-2222-bbbb-3333cccc4444",
  "Domain": "contoso.onmicrosoft.com",
  "Instance": "https://login.microsoftonline.com/",
  "ResponseType": "code",
  "TenantId": "aaaabbbb-0000-cccc-1111-dddd2222eeee"
},
```

The callback path (`CallbackPath`) must match the redirect URI (login callback path) configured when registering the application in the Entra or Azure portal. Paths are configured in the **Authentication** blade of the app's registration. The default value of `CallbackPath` is `/signin-oidc` for a registered redirect URI of `https://localhost/signin-oidc` (a port isn't required).

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data.

Redirect to the home page on sign out

When a user navigates around the app, the `LogInOrOut` component (`Layout/LogInOrOut.razor`) sets a hidden field for the return URL (`ReturnUrl`) to the value of the current URL (`currentURL`). When the user signs out of the app, the identity provider returns them to the page from which they signed out.

If the user signs out from a secure page, they're returned back to the same secure page after signing out only to be sent back through the authentication process. This behavior is fine when users need to switch accounts frequently. However, a alternative app specification may call for the user to be returned to the app's home page or some other page after signing out. The following example shows how to set the app's home page as the return URL for sign-out operations.

The important changes to the `LogInOrOut` component are demonstrated in the following example. There's no need to provide a hidden field for the `ReturnUrl` set to the home page at `/` because that's the default path. IDisposable is no longer implemented. The NavigationManager is no longer injected. The entire `@code` block is removed.

`Layout/LogInOrOut.razor`:

razor

```
@using Microsoft.AspNetCore.Authorization

<div class="nav-item px-3">
    <AuthorizeView>
        <Authorized>
            <form action="authentication/logout" method="post">
                <AntiforgeryToken />
                <button type="submit" class="nav-link">
                    <span class="bi bi-arrow-bar-left-nav-menu" aria-
hidden="true">
                    </span> Logout @context.User.Identity?.Name
                </button>
            </form>
        </Authorized>
        <NotAuthorized>
            <a class="nav-link" href="authentication/login">
                <span class="bi bi-person-badge-nav-menu" aria-
hidden="true"></span>
                Login
            </a>
        </NotAuthorized>
    </AuthorizeView>
</div>
```

Troubleshoot

Logging

The server app is a standard ASP.NET Core app. See the ASP.NET Core logging guidance to enable a lower logging level in the server app.

To enable debug or trace logging for Blazor WebAssembly authentication, see the *Client-side authentication logging* section of ASP.NET Core Blazor logging with the article version selector set to ASP.NET Core 7.0 or later.

Common errors

- Misconfiguration of the app or Identity Provider (IP)

  The most common errors are caused by incorrect configuration. The following are a few examples:
  - Depending on the requirements of the scenario, a missing or incorrect Authority, Instance, Tenant ID, Tenant domain, Client ID, or Redirect URI prevents an app from authenticating clients.
  - Incorrect request scopes prevent clients from accessing server web API endpoints.
  - Incorrect or missing server API permissions prevent clients from accessing server web API endpoints.
  - Running the app at a different port than is configured in the Redirect URI of the IP's app registration. Note that a port isn't required for Microsoft Entra ID and an app running at a `localhost` development testing address, but the app's port configuration and the port where the app is running must match for non-`localhost` addresses.

  Configuration coverage in this article shows examples of the correct configuration. Carefully check the configuration looking for app and IP misconfiguration.

  If the configuration appears correct:

  - Analyze application logs.

  - Examine the network traffic between the client app and the IP or server app with the browser's developer tools. Often, an exact error message or a message with a clue to what's causing the problem is returned to the client by the IP or server app after making a request. Developer tools guidance is found in the following articles:
    - Google Chrome (Google documentation)
    - Microsoft Edge
    - Mozilla Firefox (Mozilla documentation)

  The documentation team responds to document feedback and bugs in articles (open an issue from the **This page** feedback section) but is unable to provide product support. Several public support forums are available to assist with troubleshooting an app. We recommend the following:
  - Stack Overflow (tag: blazor)
  - ASP.NET Core Slack Team
  - Blazor Gitter

  The preceding forums are not owned or controlled by Microsoft.

For non-security, non-sensitive, and non-confidential reproducible framework bug reports, open an issue with the ASP.NET Core product unit. Don't open an issue with the product unit until you've thoroughly investigated the cause of a problem and can't resolve it on your own and with the help of the community on a public support forum. The product unit isn't able to troubleshoot individual apps that are broken due to simple misconfiguration or use cases involving third-party services. If a report is sensitive or confidential in nature or describes a potential security flaw in the product that cyberattackers may exploit, see Reporting security issues and bugs (dotnet/aspnetcore GitHub repository).

- Unauthorized client for ME-ID

  > info: Microsoft.AspNetCore.Authorization.DefaultAuthorizationService[2]
  > Authorization failed. These requirements were not met:
  > DenyAnonymousAuthorizationRequirement: Requires an authenticated user.

  Login callback error from ME-ID:
  - Error: `unauthorized_client`
  - Description: `AADB2C90058: The provided application is not configured to allow public clients.`

  To resolve the error:

  1. In the Azure portal, access the app's manifest.
  2. Set the allowPublicClient attribute to `null` or `true`.

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.

    - Make sure that the browser is closed manually or by the IDE for any change to the app, test user, or provider configuration.
- Use a custom command to open a browser in InPrivate or Incognito mode in Visual Studio:
    - Open **Browse With** dialog box from Visual Studio's **Run** button.
    - Select the **Add** button.
    - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
        - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
        - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
        - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
    - In the **Arguments** field, provide the command-line option that the browser uses to open in InPrivate or Incognito mode. Some browsers require the URL of the app.
        - Microsoft Edge: Use `-inprivate`.
        - Google Chrome: Use `--incognito --new-window {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
        - Mozilla Firefox: Use `-private -url {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
    - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
    - Select the **OK** button.
    - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
    - Make sure that the browser is closed by the IDE for any change to the app, test user, or provider configuration.

App upgrades

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Clear the local system's NuGet package caches by executing dotnet nuget locals all --clear from a command shell.
2. Delete the project's `bin` and `obj` folders.

3. Restore and rebuild the project.
4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

> **Note**
>
> Use of package versions incompatible with the app's target framework isn't supported. For information on a package, use the NuGet Gallery or FuGet Package Explorer.

Run the server app

When testing and troubleshooting Blazor Web App, make sure that you're running the app from the server project.

Inspect the user

The following `UserClaims` component can be used directly in apps or serve as the basis for further customization.

`UserClaims.razor`:

razor

```
@page "/user-claims"
@using System.Security.Claims
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize]

<PageTitle>User Claims</PageTitle>

<h1>User Claims</h1>

@if (claims.Any())
{
    <ul>
        @foreach (var claim in claims)
        {
            <li><b>@claim.Type:</b> @claim.Value</li>
        }
    </ul>
}

@code {
    private IEnumerable<Claim> claims = Enumerable.Empty<Claim>();
```

```
    [CascadingParameter]
    private Task<AuthenticationState>? AuthState { get; set; }

    protected override async Task OnInitializedAsync()
    {
        if (AuthState == null)
        {
            return;
        }

        var authState = await AuthState;
        claims = authState.User.Claims;
    }
}
```

Secure an ASP.NET Core Blazor Web App with OpenID Connect (OIDC)

Article • 10/25/2024

This article describes how to secure a Blazor Web App with OpenID Connect (OIDC) using a sample app in the dotnet/blazor-samples GitHub repository (.NET 8 or later) (how to download).

This version of the article covers implementing OIDC without adopting the Backend for Frontend (BFF) pattern. The BFF pattern is useful for making authenticated requests to external services. Change the article version selector to **OIDC with BFF pattern** if the app's specification calls for adopting the BFF pattern.

The following specification is covered:

- The Blazor Web App uses the Auto render mode with global interactivity.
- Custom auth state provider services are used by the server and client apps to capture the user's authentication state and flow it between the server and client.
- This app is a starting point for any OIDC authentication flow. OIDC is configured manually in the app and doesn't rely upon Microsoft Entra ID or Microsoft Identity Web packages, nor does the sample app require Microsoft Azure hosting. However, the sample app can be used with Entra, Microsoft Identity Web, and hosted in Azure.
- Automatic non-interactive token refresh.
- Securely calls a (web) API in the server project for data.

Sample app

The sample app consists of two projects:

- `BlazorWebAppOidc`: Server-side project of the Blazor Web App, containing an example Minimal API endpoint for weather data.
- `BlazorWebAppOidc.Client`: Client-side project of the Blazor Web App.

Access the sample apps through the latest version folder from the repository's root with the following link. The projects are in the `BlazorWebAppOidc` folder for .NET 8 or later.

View or download sample code (how to download)

Server-side Blazor Web App project (`BlazorWebAppOidc`)

The `BlazorWebAppOidc` project is the server-side project of the Blazor Web App.

The `BlazorWebAppOidc.http` file can be used for testing the weather data request. Note that the `BlazorWebAppOidc` project must be running to test the endpoint, and the endpoint is hardcoded into the file. For more information, see Use .http files in Visual Studio 2022.

> ⓘ **Note**
>
> The server project uses IHttpContextAccessor/HttpContext, but never for interactively-rendered components. For more information, see Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering.

Configuration

This section explains how to configure the sample app.

> ⓘ **Note**
>
> For Microsoft Entra ID or Azure AD B2C, you can use AddMicrosoftIdentityWebApp from Microsoft Identity Web (Microsoft.Identity.Web NuGet package, API documentation), which adds both the OIDC and Cookie authentication handlers with the appropriate defaults. The sample app and the guidance in this section doesn't use Microsoft Identity Web. The guidance demonstrates how to configure the OIDC handler *manually* for any OIDC provider. For more information on implementing Microsoft Identity Web, see the linked resources.

Establish the client secret

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in client-side code, which is ***always insecure***. In test/staging and production

environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

For local development testing, use the Secret Manager tool to store the server app's client secret under the configuration key `Authentication:Schemes:MicrosoftOidc:ClientSecret`.

> **Note**
>
> If the app uses Microsoft Entra ID or Azure AD B2C, create a client secret in the app's registration in the Entra or Azure portal (**Manage** > **Certificates & secrets** > **New client secret**). Use the **Value** of the new secret in the following guidance.

Execute the following command in a command shell from the server project's directory, such as the Developer PowerShell command shell in Visual Studio. The `{SECRET}` placeholder is the client secret obtained from the app's registration:

.NET CLI

```
dotnet user-secrets set "Authentication:Schemes:MicrosoftOidc:ClientSecret"
"{SECRET}"
```

If using Visual Studio, you can confirm the secret is set by right-clicking the server project in **Solution Explorer** and selecting **Manage User Secrets**.

Configure the app

The following OpenIdConnectOptions configuration is found in the project's `Program` file on the call to AddOpenIdConnect:

- SignInScheme: Sets the authentication scheme corresponding to the middleware responsible of persisting user's identity after a successful authentication. The OIDC handler needs to use a sign-in scheme that's capable of persisting user credentials across requests. The following line is present merely for demonstration purposes. If omitted, DefaultSignInScheme is used as a fallback value.

```
C#

oidcOptions.SignInScheme =
CookieAuthenticationDefaults.AuthenticationScheme;
```

- Scopes for `openid` and `profile` (Scope) (Optional): The `openid` and `profile` scopes are also configured by default because they're required for the OIDC handler to work, but these may need to be re-added if scopes are included in the `Authentication:Schemes:MicrosoftOidc:Scope` configuration. For general configuration guidance, see Configuration in ASP.NET Core and ASP.NET Core Blazor configuration.

```
C#

oidcOptions.Scope.Add(OpenIdConnectScope.OpenIdProfile);
```

- SaveTokens: Defines whether access and refresh tokens should be stored in the AuthenticationProperties after a successful authorization. This property is set to `false` to reduce the size of the final authentication cookie.

```
C#

oidcOptions.SaveTokens = false;
```

- Scope for offline access (Scope): The `offline_access` scope is required for the refresh token.

```
C#

oidcOptions.Scope.Add(OpenIdConnectScope.OfflineAccess);
```

- Authority and ClientId: Sets the Authority and Client ID for OIDC calls.

```
C#

oidcOptions.Authority = "{AUTHORITY}";
oidcOptions.ClientId = "{CLIENT ID}";
```

  Example:
  - Authority (`{AUTHORITY}`): `https://login.microsoftonline.com/aaaabbbb-0000-cccc-1111-dddd2222eeee/v2.0/` (uses Tenant ID `aaaabbbb-0000-cccc-1111-dddd2222eeee`)

- Client Id (`{CLIENT ID}`): `00001111-aaaa-2222-bbbb-3333cccc4444`

```
C#

oidcOptions.Authority = "https://login.microsoftonline.com/aaaabbbb-
0000-cccc-1111-dddd2222eeee/v2.0/";
oidcOptions.ClientId = "00001111-aaaa-2222-bbbb-3333cccc4444";
```

Example for Microsoft Azure "common" authority:

The "common" authority should be used for multi-tenant apps. You can also use the "common" authority for single-tenant apps, but a custom IssuerValidator is required, as shown later in this section.

```
C#

oidcOptions.Authority =
"https://login.microsoftonline.com/common/v2.0/";
```

- ResponseType: Configures the OIDC handler to only perform authorization code flow. Implicit grants and hybrid flows are unnecessary in this mode.

  In the Entra or Azure portal's **Implicit grant and hybrid flows** app registration configuration, do **not** select either checkbox for the authorization endpoint to return **Access tokens** or **ID tokens**. The OIDC handler automatically requests the appropriate tokens using the code returned from the authorization endpoint.

```
C#

oidcOptions.ResponseType = OpenIdConnectResponseType.Code;
```

- MapInboundClaims and configuration of NameClaimType and RoleClaimType: Many OIDC servers use "`name`" and "`role`" rather than the SOAP/WS-Fed defaults in ClaimTypes. When MapInboundClaims is set to `false`, the handler doesn't perform claims mappings, and the claim names from the JWT are used directly by the app. The following example sets the role claim type to "`roles`," which is appropriate for Microsoft Entra ID (ME-ID). Consult your identity provider's documentation for more information.

> **Note**

MapInboundClaims must be set to `false` for most OIDC providers, which prevents renaming claims.

```
C#

oidcOptions.MapInboundClaims = false;
oidcOptions.TokenValidationParameters.NameClaimType = "name";
oidcOptions.TokenValidationParameters.RoleClaimType = "roles";
```

- Path configuration: Paths must match the redirect URI (login callback path) and post logout redirect (signed-out callback path) paths configured when registering the application with the OIDC provider. In the Azure portal, paths are configured in the **Authentication** blade of the app's registration. Both the sign-in and sign-out paths must be registered as redirect URIs. The default values are `/signin-oidc` and `/signout-callback-oidc`.

  - CallbackPath: The request path within the app's base path where the user-agent is returned.

    In the Entra or Azure portal, set the path in the **Web** platform configuration's **Redirect URI**:

    > https://localhost/signin-oidc

    > **Note**
    >
    > A port isn't required for `localhost` addresses when using Microsoft Entra ID. Most other OIDC providers require a correct port.

  - SignedOutCallbackPath: The request path within the app's base path where the user agent is returned after sign out from the identity provider.

    In the Entra or Azure portal, set the path in the **Web** platform configuration's **Redirect URI**:

    > https://localhost/signout-callback-oidc

    > **Note**

A port isn't required for `localhost` addresses when using Microsoft Entra ID. Most other OIDC providers require a correct port.

> **Note**
>
> If using Microsoft Identity Web, the provider currently only redirects back to the SignedOutCallbackPath if the `microsoftonline.com` Authority (`https://login.microsoftonline.com/{TENANT ID}/v2.0/`) is used. This limitation doesn't exist if you can use the "common" Authority with Microsoft Identity Web. For more information, see postLogoutRedirectUri not working when authority url contains a tenant ID (AzureAD/microsoft-authentication-library-for-js #5783).

- RemoteSignOutPath: Requests received on this path cause the handler to invoke sign-out using the sign-out scheme.

  In the Entra or Azure portal, set the **Front-channel logout URL**:

  > https://localhost/signout-oidc

  > **Note**
  >
  > A port isn't required for `localhost` addresses when using Microsoft Entra ID. Most other OIDC providers require a correct port.

  C#

  ```
  oidcOptions.CallbackPath = new PathString("{PATH}");
  oidcOptions.SignedOutCallbackPath = new PathString("{PATH}");
  oidcOptions.RemoteSignOutPath = new PathString("{PATH}");
  ```

  Examples (default values):

  C#

  ```
  oidcOptions.CallbackPath = new PathString("/signin-oidc");
  oidcOptions.SignedOutCallbackPath = new PathString("/signout-
  callback-oidc");
  oidcOptions.RemoteSignOutPath = new PathString("/signout-oidc");
  ```

- (*Microsoft Azure only with the "common" endpoint*) TokenValidationParameters.IssuerValidator: Many OIDC providers work with the default issuer validator, but we need to account for the issuer parameterized with the Tenant ID (`{TENANT ID}`) returned by `https://login.microsoftonline.com/common/v2.0/.well-known/openid-configuration`. For more information, see SecurityTokenInvalidIssuerException with OpenID Connect and the Azure AD "common" endpoint (AzureAD/azure-activedirectory-identitymodel-extensions-for-dotnet #1731).

  Only for apps using Microsoft Entra ID or Azure AD B2C with the "common" endpoint:

  ```
  C#

  var microsoftIssuerValidator =
  AadIssuerValidator.GetAadIssuerValidator(oidcOptions.Authority);
  oidcOptions.TokenValidationParameters.IssuerValidator =
  microsoftIssuerValidator.Validate;
  ```

Sample app code

Inspect the sample app for the following features:

- Automatic non-interactive token refresh with the help of a custom cookie refresher (`CookieOidcRefresher.cs`).
- The server project calls `AddAuthenticationStateSerialization` to add a server-side authentication state provider that uses PersistentComponentState to flow the authentication state to the client. The client calls `AddAuthenticationStateDeserialization` to deserialize and use the authentication state passed by the server. The authentication state is fixed for the lifetime of the WebAssembly application.
- An example requests to the Blazor Web App for weather data is handled by a Minimal API endpoint (`/weather-forecast`) in the `Program` file (`Program.cs`). The endpoint requires authorization by calling RequireAuthorization. For any controllers that you add to the project, add the [Authorize] attribute to the controller or action.
- The app securely calls a (web) API in the server project for weather data:
  - When rendering the `Weather` component on the server, the component uses the `ServerWeatherForecaster` on the server to obtain weather data directly (not via a web API call).

- When the component is rendered on the client, the component uses the `ClientWeatherForecaster` service implementation, which uses a preconfigured HttpClient (in the client project's `Program` file) to make a web API call to the server project. A Minimal API endpoint (`/weather-forecast`) defined in the server project's `Program` file obtains the weather data from the `ServerWeatherForecaster` and returns the data to the client.

For more information on (web) API calls using a service abstractions in Blazor Web Apps, see Call a web API from an ASP.NET Core Blazor app.

Client-side Blazor Web App project (`BlazorWebAppOidc.Client`)

The `BlazorWebAppOidc.Client` project is the client-side project of the Blazor Web App.

The client calls `AddAuthenticationStateDeserialization` to deserialize and use the authentication state passed by the server. The authentication state is fixed for the lifetime of the WebAssembly application.

If the user needs to log in or out, a full page reload is required.

The sample app only provides a user name and email for display purposes. It doesn't include tokens that authenticate to the server when making subsequent requests, which works separately using a cookie that's included on HttpClient requests to the server.

Adding components that adopt interactive server-side rendering

Because the app uses global Interactive Auto rendering via the `Routes` component, individual components that specify interactive server-side rendering (interactive SSR, `@rendermode InteractiveServer`) in their component definition file (`.razor`) are *placed in the `.Client` project's `Pages` folder*.

Placing interactive SSR components in the `.Client` project is counter-intuitive because such components are only rendered on the server.

If you place an interactive SSR component in the server project's `Components/Pages` folder, the component is prerendered normally and briefly displayed in the user's browser. However, the client-side router isn't able to find the component, ultimately resulting in a *404 - Not Found* in the browser.

Therefore, place interactive SSR components in the `.Client` project's `Pages` folder.

Redirect to the home page on signout

When a user navigates around the app, the `LogInOrOut` component (`Layout/LogInOrOut.razor`) sets a hidden field for the return URL (`ReturnUrl`) to the value of the current URL (`currentURL`). When the user signs out of the app, the identity provider returns them to the page from which they signed out.

If the user signs out from a secure page, they're returned back to the same secure page after signing out only to be sent back through the authentication process. This behavior is fine when users need to switch accounts frequently. However, a alternative app specification may call for the user to be returned to the app's home page or some other page after signout. The following example shows how to set the app's home page as the return URL for signout operations.

The important changes to the `LogInOrOut` component are demonstrated in the following example. There's no need to provide a hidden field for the `ReturnUrl` set to the home page at `/` because that's the default path. IDisposable is no longer implemented. The NavigationManager is no longer injected. The entire `@code` block is removed.

`Layout/LogInOrOut.razor`:

razor

```
@using Microsoft.AspNetCore.Authorization

<div class="nav-item px-3">
    <AuthorizeView>
        <Authorized>
            <form action="authentication/logout" method="post">
                <AntiforgeryToken />
                <button type="submit" class="nav-link">
                    <span class="bi bi-arrow-bar-left-nav-menu" aria-
hidden="true">
                    </span> Logout @context.User.Identity?.Name
                </button>
            </form>
        </Authorized>
        <NotAuthorized>
            <a class="nav-link" href="authentication/login">
                <span class="bi bi-person-badge-nav-menu" aria-
hidden="true"></span>
                Login
            </a>
        </NotAuthorized>
```

```
    </AuthorizeView>
</div>
```

Cryptographic nonce

A *nonce* is a string value that associates a client's session with an ID token to mitigate replay attacks.

If you receive a nonce error during authentication development and testing, use a new InPrivate/incognito browser session for each test run, no matter how small the change made to the app or test user because stale cookie data can lead to a nonce error. For more information, see the Cookies and site data section.

A nonce isn't required or used when a refresh token is exchanged for a new access token. In the sample app, the `CookieOidcRefresher` (`CookieOidcRefresher.cs`) deliberately sets OpenIdConnectProtocolValidator.RequireNonce to `false`.

Application roles for apps not registered with Microsoft Entra (ME-ID)

This section pertains to apps that don't use Microsoft Entra ID (ME-ID) as the identity provider. For apps registered with ME-ID, see the Application roles for apps registered with Microsoft Entra (ME-ID) section.

Configure the role claim type (TokenValidationParameters.RoleClaimType) in the OpenIdConnectOptions of `Program.cs`:

C#

```
oidcOptions.TokenValidationParameters.RoleClaimType = "{ROLE CLAIM TYPE}";
```

For many OIDC identity providers, the role claim type is `role`. Check your identity provider's documentation for the correct value.

Replace the `UserInfo` class in the `BlazorWebAppOidc.Client` project with the following class.

`UserInfo.cs`:

C#

```
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using System.Security.Claims;

namespace BlazorWebAppOidc.Client;

// Add properties to this class and update the server and client
// AuthenticationStateProviders to expose more information about
// the authenticated user to the client.
public sealed class UserInfo
{
    public required string UserId { get; init; }
    public required string Name { get; init; }
    public required string[] Roles { get; init; }

    public const string UserIdClaimType = "sub";
    public const string NameClaimType = "name";
    private const string RoleClaimType = "role";

    public static UserInfo FromClaimsPrincipal(ClaimsPrincipal principal) =>
        new()
        {
            UserId = GetRequiredClaim(principal, UserIdClaimType),
            Name = GetRequiredClaim(principal, NameClaimType),
            Roles = principal.FindAll(RoleClaimType).Select(c => c.Value)
                .ToArray(),
        };

    public ClaimsPrincipal ToClaimsPrincipal() =>
        new(new ClaimsIdentity(
            Roles.Select(role => new Claim(RoleClaimType, role))
                .Concat([
                    new Claim(UserIdClaimType, UserId),
                    new Claim(NameClaimType, Name),
                ]),
            authenticationType: nameof(UserInfo),
            nameType: NameClaimType,
            roleType: RoleClaimType));

    private static string GetRequiredClaim(ClaimsPrincipal principal,
        string claimType) =>
            principal.FindFirst(claimType)?.Value ??
            throw new InvalidOperationException(
                $"Could not find required '{claimType}' claim.");
}
```

At this point, Razor components can adopt role-based and policy-based authorization. Application roles appear in `role` claims, one claim per role.

Application roles for apps registered with Microsoft Entra (ME-ID)

Use the guidance in this section to implement application roles, ME-ID security groups, and ME-ID built-in administrator roles for apps using Microsoft Entra ID (ME-ID).

The approach described in this section configures ME-ID to send groups and roles in the authentication cookie header. When users are only a member of a few security groups and roles, the following approach should work for most hosting platforms without running into a problem where headers are too long, for example with IIS hosting that has a default header length limit of 16 KB (`MaxRequestBytes`). If header length is a problem due to high group or role membership, we recommend not following the guidance in this section in favor of implementing Microsoft Graph to obtain a user's groups and roles from ME-ID separately, an approach that doesn't inflate the size of the authentication cookie. For more information, see Bad Request - Request Too Long - IIS Server (dotnet/aspnetcore #57545).

Configure the role claim type (TokenValidationParameters.RoleClaimType) in OpenIdConnectOptions of `Program.cs`. Set the value to `roles`:

```
C#

oidcOptions.TokenValidationParameters.RoleClaimType = "roles";
```

Although you can't assign roles to groups without an ME-ID Premium account, you can assign roles to users and receive role claims for users with a standard Azure account. The guidance in this section doesn't require an ME-ID Premium account.

When working with the default directory, follow the guidance in Add app roles to your application and receive them in the token (ME-ID documentation) to configure and assign roles. If you aren't working with the default directory, edit the app's manifest in the Azure portal to establish the app's roles manually in the `appRoles` entry of the manifest file. For more information, see Configure the role claim (ME-ID documentation).

A user's Azure security groups arrive in `groups` claims, and a user's built-in ME-ID administrator role assignments arrive in well-known IDs (wids) claims. Values for both claim types are GUIDs. When received by the app, these claims can be used to establish role and policy authorization in Razor components.

In the app's manifest in the Azure portal, set the groupMembershipClaims attribute to `All`. A value of `All` results in ME-ID sending all of the security/distribution groups (`groups` claims) and roles (`wids` claims) of the signed-in user. To set the `groupMembershipClaims` attribute:

1. Open the app's registration in the Azure portal.

2. Select **Manage** > **Manifest** in the sidebar.
3. Find the `groupMembershipClaims` attribute.
4. Set the value to `All` (`"groupMembershipClaims": "All"`).
5. Select the **Save** button.

Replace the `UserInfo` class in the `BlazorWebAppOidc.Client` project with the following class.

`UserInfo.cs`:

C#

```
using Microsoft.AspNetCore.Components.WebAssembly.Authentication;
using System.Security.Claims;

namespace BlazorWebAppOidc.Client;

// Add properties to this class and update the server and client
// AuthenticationStateProviders to expose more information about
// the authenticated user to the client.
public sealed class UserInfo
{
    public required string UserId { get; init; }
    public required string Name { get; init; }
    public required string[] Roles { get; init; }
    public required string[] Groups { get; init; }
    public required string[] Wids { get; init; }

    public const string UserIdClaimType = "sub";
    public const string NameClaimType = "name";
    private const string RoleClaimType = "roles";
    private const string GroupsClaimType = "groups";
    private const string WidsClaimType = "wids";

    public static UserInfo FromClaimsPrincipal(ClaimsPrincipal principal) =>
        new()
        {
            UserId = GetRequiredClaim(principal, UserIdClaimType),
            Name = GetRequiredClaim(principal, NameClaimType),
            Roles = principal.FindAll(RoleClaimType).Select(c => c.Value)
                .ToArray(),
            Groups = principal.FindAll(GroupsClaimType).Select(c => c.Value)
                .ToArray(),
            Wids = principal.FindAll(WidsClaimType).Select(c => c.Value)
                .ToArray(),
        };

    public ClaimsPrincipal ToClaimsPrincipal() =>
        new(new ClaimsIdentity(
            Roles.Select(role => new Claim(RoleClaimType, role))
                .Concat(Groups.Select(role => new Claim(GroupsClaimType,
role)))
```

```
                .Concat(Wids.Select(role => new Claim(WidsClaimType, role)))
                .Concat([
                    new Claim(UserIdClaimType, UserId),
                    new Claim(NameClaimType, Name),
                ]),
            authenticationType: nameof(UserInfo),
            nameType: NameClaimType,
            roleType: RoleClaimType));

    private static string GetRequiredClaim(ClaimsPrincipal principal,
        string claimType) =>
            principal.FindFirst(claimType)?.Value ??
            throw new InvalidOperationException(
                $"Could not find required '{claimType}' claim.");
}
```

At this point, Razor components can adopt role-based and policy-based authorization:

- Application roles appear in `roles` claims, one claim per role.
- Security groups appear in `groups` claims, one claim per group. The security group GUIDs appear in the Azure portal when you create a security group and are listed when selecting **Identity** > **Overview** > **Groups** > **View**.
- Built-in ME-ID administrator roles appear in `wids` claims, one claim per role. The `wids` claim with a value of `b79fbf4d-3ef9-4689-8143-76b194e85509` is always sent by ME-ID for non-guest accounts of the tenant and doesn't refer to an administrator role. Administrator role GUIDs (*role template IDs*) appear in the Azure portal when selecting **Roles & admins**, followed by the ellipsis (...) > **Description** for the listed role. The role template IDs are also listed in Microsoft Entra built-in roles (Entra documentation).

Troubleshoot

Logging

The server app is a standard ASP.NET Core app. See the ASP.NET Core logging guidance to enable a lower logging level in the server app.

To enable debug or trace logging for Blazor WebAssembly authentication, see the *Client-side authentication logging* section of ASP.NET Core Blazor logging with the article version selector set to ASP.NET Core 7.0 or later.

Common errors

- Misconfiguration of the app or Identity Provider (IP)

The most common errors are caused by incorrect configuration. The following are a few examples:

- Depending on the requirements of the scenario, a missing or incorrect Authority, Instance, Tenant ID, Tenant domain, Client ID, or Redirect URI prevents an app from authenticating clients.
- Incorrect request scopes prevent clients from accessing server web API endpoints.
- Incorrect or missing server API permissions prevent clients from accessing server web API endpoints.
- Running the app at a different port than is configured in the Redirect URI of the IP's app registration. Note that a port isn't required for Microsoft Entra ID and an app running at a `localhost` development testing address, but the app's port configuration and the port where the app is running must match for non-`localhost` addresses.

Configuration coverage in this article shows examples of the correct configuration. Carefully check the configuration looking for app and IP misconfiguration.

If the configuration appears correct:

- Analyze application logs.

- Examine the network traffic between the client app and the IP or server app with the browser's developer tools. Often, an exact error message or a message with a clue to what's causing the problem is returned to the client by the IP or server app after making a request. Developer tools guidance is found in the following articles:
  - Google Chrome (Google documentation)
  - Microsoft Edge
  - Mozilla Firefox (Mozilla documentation)

The documentation team responds to document feedback and bugs in articles (open an issue from the **This page** feedback section) but is unable to provide product support. Several public support forums are available to assist with troubleshooting an app. We recommend the following:

- Stack Overflow (tag: blazor)
- ASP.NET Core Slack Team
- Blazor Gitter

The preceding forums are not owned or controlled by Microsoft.

For non-security, non-sensitive, and non-confidential reproducible framework bug reports, open an issue with the ASP.NET Core product unit. Don't open an issue

with the product unit until you've thoroughly investigated the cause of a problem and can't resolve it on your own and with the help of the community on a public support forum. The product unit isn't able to troubleshoot individual apps that are broken due to simple misconfiguration or use cases involving third-party services. If a report is sensitive or confidential in nature or describes a potential security flaw in the product that cyberattackers may exploit, see Reporting security issues and bugs (dotnet/aspnetcore GitHub repository).

- Unauthorized client for ME-ID

  > info: Microsoft.AspNetCore.Authorization.DefaultAuthorizationService[2]
  > Authorization failed. These requirements were not met:
  > DenyAnonymousAuthorizationRequirement: Requires an authenticated user.

  Login callback error from ME-ID:
  - Error: `unauthorized_client`
  - Description: `AADB2C90058: The provided application is not configured to allow public clients.`

  To resolve the error:

  1. In the Azure portal, access the app's manifest.
  2. Set the allowPublicClient attribute to `null` or `true`.

Cookies and site data

Cookies and site data can persist across app updates and interfere with testing and troubleshooting. Clear the following when making app code changes, user account changes with the provider, or provider app configuration changes:

- User sign-in cookies
- App cookies
- Cached and stored site data

One approach to prevent lingering cookies and site data from interfering with testing and troubleshooting is to:

- Configure a browser
  - Use a browser for testing that you can configure to delete all cookie and site data each time the browser is closed.
  - Make sure that the browser is closed manually or by the IDE for any change to the app, test user, or provider configuration.

- Use a custom command to open a browser in InPrivate or Incognito mode in Visual Studio:
  - Open **Browse With** dialog box from Visual Studio's **Run** button.
  - Select the **Add** button.
  - Provide the path to your browser in the **Program** field. The following executable paths are typical installation locations for Windows 10. If your browser is installed in a different location or you aren't using Windows 10, provide the path to the browser's executable.
    - Microsoft Edge: `C:\Program Files (x86)\Microsoft\Edge\Application\msedge.exe`
    - Google Chrome: `C:\Program Files (x86)\Google\Chrome\Application\chrome.exe`
    - Mozilla Firefox: `C:\Program Files\Mozilla Firefox\firefox.exe`
  - In the **Arguments** field, provide the command-line option that the browser uses to open in InPrivate or Incognito mode. Some browsers require the URL of the app.
    - Microsoft Edge: Use `-inprivate`.
    - Google Chrome: Use `--incognito --new-window {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
    - Mozilla Firefox: Use `-private -url {URL}`, where the `{URL}` placeholder is the URL to open (for example, `https://localhost:5001`).
  - Provide a name in the **Friendly name** field. For example, `Firefox Auth Testing`.
  - Select the **OK** button.
  - To avoid having to select the browser profile for each iteration of testing with an app, set the profile as the default with the **Set as Default** button.
  - Make sure that the browser is closed by the IDE for any change to the app, test user, or provider configuration.

App upgrades

A functioning app may fail immediately after upgrading either the .NET Core SDK on the development machine or changing package versions within the app. In some cases, incoherent packages may break an app when performing major upgrades. Most of these issues can be fixed by following these instructions:

1. Clear the local system's NuGet package caches by executing dotnet nuget locals all --clear from a command shell.
2. Delete the project's `bin` and `obj` folders.
3. Restore and rebuild the project.

4. Delete all of the files in the deployment folder on the server prior to redeploying the app.

> **Note**
>
> Use of package versions incompatible with the app's target framework isn't supported. For information on a package, use the NuGet Gallery or FuGet Package Explorer.

Run the server app

When testing and troubleshooting Blazor Web App, make sure that you're running the app from the server project.

Inspect the user

The following `UserClaims` component can be used directly in apps or serve as the basis for further customization.

`UserClaims.razor`:

razor

```
@page "/user-claims"
@using System.Security.Claims
@using Microsoft.AspNetCore.Authorization
@attribute [Authorize]

<PageTitle>User Claims</PageTitle>

<h1>User Claims</h1>

@if (claims.Any())
{
    <ul>
        @foreach (var claim in claims)
        {
            <li><b>@claim.Type:</b> @claim.Value</li>
        }
    </ul>
}

@code {
    private IEnumerable<Claim> claims = Enumerable.Empty<Claim>();

    [CascadingParameter]
    private Task<AuthenticationState>? AuthState { get; set; }
```

```
    protected override async Task OnInitializedAsync()
    {
        if (AuthState == null)
        {
            return;
        }

        var authState = await AuthState;
        claims = authState.User.Claims;
    }
}
```

Enforce a Content Security Policy for ASP.NET Core Blazor

Article • 09/27/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to use a Content Security Policy (CSP) with ASP.NET Core Blazor apps to help protect against Cross-Site Scripting (XSS) attacks.

Cross-Site Scripting (XSS) is a security vulnerability where a cyberattacker places one or more malicious client-side scripts into an app's rendered content. A CSP helps protect against XSS attacks by informing the browser of valid:

- Sources for loaded content, including scripts, stylesheets, images, and plugins.
- Actions taken by a page, specifying permitted URL targets of forms.

To apply a CSP to an app, the developer specifies several CSP content security *directives* in one or more `Content-Security-Policy` headers or `<meta>` tags. For guidance on applying a CSP to an app in C# code at startup, see ASP.NET Core Blazor startup.

Policies are evaluated by the browser while a page is loading. The browser inspects the page's sources and determines if they meet the requirements of the content security directives. When policy directives aren't met for a resource, the browser doesn't load the resource. For example, consider a policy that doesn't allow third-party scripts. When a page contains a `<script>` tag with a third-party origin in the `src` attribute, the browser prevents the script from loading.

CSP is supported in most modern desktop and mobile browsers, including Chrome, Edge, Firefox, Opera, and Safari. CSP is recommended for Blazor apps.

Policy directives

Minimally, specify the following directives and sources for Blazor apps. Add additional directives and sources as needed. The following directives are used in the *Apply the*

policy section of this article, where example security policies for Blazor apps are provided:

- base-uri: Restricts the URLs for a page's `<base>` tag. Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
- default-src: Indicates a fallback for source directives that aren't explicitly specified by the policy. Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
- img-src: Indicates valid sources for images.
  - Specify `data:` to permit loading images from `data:` URLs.
  - Specify `https:` to permit loading images from HTTPS endpoints.
- object-src: Indicates valid sources for the `<object>`, `<embed>`, and `<applet>` tags. Specify `none` to prevent all URL sources.
- script-src: Indicates valid sources for scripts.
  - Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
  - In a client-side Blazor app:
    - Specify wasm-unsafe-eval to permit the client-side Blazor Mono runtime to function.
    - Specify any additional hashes to permit your required *non-framework scripts* to load.
  - In a server-side Blazor app, specify hashes to permit required scripts to load.
- style-src: Indicates valid sources for stylesheets.
  - Specify `self` to indicate that the app's origin, including the scheme and port number, is a valid source.
  - If the app uses inline styles, specify `unsafe-inline` to allow the use of your inline styles.
- upgrade-insecure-requests: Indicates that content URLs from insecure (HTTP) sources should be acquired securely over HTTPS.

The preceding directives are supported by all browsers except Microsoft Internet Explorer.

To obtain SHA hashes for additional inline scripts:

- Apply the CSP shown in the *Apply the policy* section.
- Access the browser's developer tools console while running the app locally. The browser calculates and displays hashes for blocked scripts when a CSP header or `meta` tag is present.
- Copy the hashes provided by the browser to the `script-src` sources. Use single quotes around each hash.

For a Content Security Policy Level 2 browser support matrix, see Can I use: Content Security Policy Level 2.

Apply the policy

Use a `<meta>` tag to apply the policy:

- Set the value of the `http-equiv` attribute to `Content-Security-Policy`.
- Place the directives in the `content` attribute value. Separate directives with a semicolon (`;`).
- Always place the `meta` tag in the <head> content.

The following sections show example policies. These examples are versioned with this article for each release of Blazor. To use a version appropriate for your release, select the document version with the **Version** dropdown selector on this webpage.

Server-side Blazor apps

In the <head> content, apply the directives described in the *Policy directives* section:

HTML

```
<meta http-equiv="Content-Security-Policy"
      content="base-uri 'self';
               default-src 'self';
               img-src data: https:;
               object-src 'none';
               script-src 'self';
               style-src 'self';
               upgrade-insecure-requests;">
```

Add additional `script-src` and `style-src` hashes as required by the app. During development, use an online tool or browser developer tools to have the hashes calculated for you. For example, the following browser tools console error reports the hash for a required script not covered by the policy:

> Refused to execute inline script because it violates the following Content Security Policy directive: " ... ". Either the 'unsafe-inline' keyword, a hash ('sha256-v8v3RKRPmN4odZ1CWM5gw80QKPCCWMcpNeOmimNL2AA='), or a nonce ('nonce-...') is required to enable inline execution.

The particular script associated with the error is displayed in the console next to the error.

Client-side Blazor apps

In the <head> content, apply the directives described in the *Policy directives* section:

HTML

```
<meta http-equiv="Content-Security-Policy"
      content="base-uri 'self';
               default-src 'self';
               img-src data: https:;
               object-src 'none';
               script-src 'self'
                          'wasm-unsafe-eval';
               style-src 'self';
               upgrade-insecure-requests;">
```

Add additional `script-src` and `style-src` hashes as required by the app. During development, use an online tool or browser developer tools to have the hashes calculated for you. For example, the following browser tools console error reports the hash for a required script not covered by the policy:

> Refused to execute inline script because it violates the following Content Security Policy directive: " ... ". Either the 'unsafe-inline' keyword, a hash ('sha256-v8v3RKRPmN4odZ1CWM5gw80QKPCCWMcpNeOmimNL2AA='), or a nonce ('nonce-...') is required to enable inline execution.

The particular script associated with the error is displayed in the console next to the error.

Apply a CSP in non-`Development` environments

When a CSP is applied to a Blazor app's `<head>` content, it interferes with local testing in the `Development` environment. For example, Browser Link and the browser refresh script fail to load. The following examples demonstrate how to apply the CSP's `<meta>` tag in non-`Development` environments.

> **Note**
>
> The examples in this section don't show the full `<meta>` tag for the CSPs. The complete `<meta>` tags are found in the subsections of the Apply the policy section earlier in this article.

Three general approaches are available:

- Apply the CSP via the `App` component, which applies the CSP to all layouts of the app.
- If you need to apply CSPs to different areas of the app, for example a custom CSP for only the admin pages, apply the CSPs on a per-layout basis using the `<HeadContent>` tag. For complete effectiveness, every app layout file must adopt the approach.
- The hosting service or server can provide a CSP via a Content-Security-Policy header added an app's outgoing responses. Because this approach varies by hosting service or server, it isn't addressed in the following examples. If you wish to adopt this approach, consult the documentation for your hosting service provider or server.

Blazor Web App approaches

In the `App` component (`Components/App.razor`), inject IHostEnvironment:

razor

```
@inject IHostEnvironment Env
```

In the `App` component's `<head>` content, apply the CSP when not in the `Development` environment:

razor

```
@if (!Env.IsDevelopment())
{
    <meta ...>
}
```

Alternatively, apply CSPs on a per-layout basis in the `Components/Layout` folder, as the following example demonstrates. Make sure that every layout specifies a CSP.

razor

```
@inject IHostEnvironment Env

@if (!Env.IsDevelopment())
{
    <HeadContent>
        <meta ...>
```

```
    </HeadContent>
}
```

Blazor WebAssembly app approaches

In the `App` component (`App.razor`), inject IWebAssemblyHostEnvironment:

razor

```
@using Microsoft.AspNetCore.Components.WebAssembly.Hosting
@inject IWebAssemblyHostEnvironment Env
```

In the `App` component's `<head>` content, apply the CSP when not in the `Development` environment:

razor

```
@if (!Env.IsDevelopment())
{
    <HeadContent>
        <meta ...>
    </HeadContent>
}
```

Alternatively, use the preceding code but apply CSPs on a per-layout basis in the `Layout` folder. Make sure that every layout specifies a CSP.

Meta tag limitations

A `<meta>` tag policy doesn't support the following directives:

- frame-ancestors
- report-to
- report-uri
- sandbox

To support the preceding directives, use a header named `Content-Security-Policy`. The directive string is the header's value.

Test a policy and receive violation reports

Testing helps confirm that third-party scripts aren't inadvertently blocked when building an initial policy.

To test a policy over a period of time without enforcing the policy directives, set the `<meta>` tag's `http-equiv` attribute or header name of a header-based policy to `Content-Security-Policy-Report-Only`. Failure reports are sent as JSON documents to a specified URL. For more information, see MDN web docs: Content-Security-Policy-Report-Only.

For reporting on violations while a policy is active, see the following articles:

- report-to
- report-uri

Although `report-uri` is no longer recommended for use, both directives should be used until `report-to` is supported by all of the major browsers. Don't exclusively use `report-uri` because support for `report-uri` is subject to being dropped *at any time* from browsers. Remove support for `report-uri` in your policies when `report-to` is fully supported. To track adoption of `report-to`, see Can I use: report-to.

Test and update an app's policy every release.

Troubleshoot

- Errors appear in the browser's developer tools console. Browsers provide information about:
  - Elements that don't comply with the policy.
  - How to modify the policy to allow for a blocked item.
- A policy is only completely effective when the client's browser supports all of the included directives. For a current browser support matrix, see Can I use: Content-Security-Policy.

> For the current release, see the .NET 8 version of this article.

This article describes common approaches for maintaining a user's data (state) while they use an app and across browser sessions.

> **Note**
>
> The code examples in this article adopt nullable reference types (NRTs) and .NET compiler null-state static analysis, which are supported in ASP.NET Core in .NET 6 or later. When targeting ASP.NET Core 5.0 or earlier, remove the null type designation (`?`) from types in the article's examples.

Maintain user state

Server-side Blazor is a stateful app framework. Most of the time, the app maintains a connection to the server. The user's state is held in the server's memory in a *circuit*.

Examples of user state held in a circuit include:

- The hierarchy of component instances and their most recent render output in the rendered UI.
- The values of fields and properties in component instances.
- Data held in dependency injection (DI) service instances that are scoped to the circuit.

User state might also be found in JavaScript variables in the browser's memory set via JavaScript interop calls.

If a user experiences a temporary network connection loss, Blazor attempts to reconnect the user to their original circuit with their original state. However, reconnecting a user to their original circuit in the server's memory isn't always possible:

- The server can't retain a disconnected circuit forever. The server must release a disconnected circuit after a timeout or when the server is under memory pressure.
- In multi-server, load-balanced deployment environments, individual servers may fail or be automatically removed when no longer required to handle the overall volume of requests. The original server processing requests for a user may become unavailable when the user attempts to reconnect.
- The user might close and reopen their browser or reload the page, which removes any state held in the browser's memory. For example, JavaScript variable values set through JavaScript interop calls are lost.

When a user can't be reconnected to their original circuit, the user receives a new circuit with an empty state. This is equivalent to closing and reopening a desktop app.

Persist state across circuits

Generally, maintain state across circuits where users are actively creating data, not simply reading data that already exists.

To preserve state across circuits, the app must persist the data to some other storage location than the server's memory. State persistence isn't automatic. You must take steps when developing the app to implement stateful data persistence.

Data persistence is typically only required for high-value state that users expended effort to create. In the following examples, persisting state either saves time or aids in commercial activities:

- Multi-step web forms: It's time-consuming for a user to re-enter data for several completed steps of a multi-step web form if their state is lost. A user loses state in this scenario if they navigate away from the form and return later.
- Shopping carts: Any commercially important component of an app that represents potential revenue can be maintained. A user who loses their state, and thus their shopping cart, may purchase fewer products or services when they return to the site later.

An app can only persist *app state*. UIs can't be persisted, such as component instances and their render trees. Components and render trees aren't generally serializable. To persist UI state, such as the expanded nodes of a tree view control, the app must use custom code to model the behavior of the UI state as serializable app state.

Where to persist state

Common locations exist for persisting state:

- Server-side storage
- URL
- Browser storage
- In-memory state container service

Server-side storage

For permanent data persistence that spans multiple users and devices, the app can use server-side storage. Options include:

- Blob storage
- Key-value storage
- Relational database
- Table storage

After data is saved, the user's state is retained and available in any new circuit.

For more information on Azure data storage options, see the following:

- Azure Databases
- Azure Storage Documentation

URL

For transient data representing navigation state, model the data as a part of the URL. Examples of user state modeled in the URL include:

- The ID of a viewed entity.
- The current page number in a paged grid.

The contents of the browser's address bar are retained:

- If the user manually reloads the page.
- If the web server becomes unavailable, and the user is forced to reload the page in order to connect to a different server.

For information on defining URL patterns with the @page directive, see ASP.NET Core Blazor routing and navigation.

Browser storage

For transient data that the user is actively creating, a commonly used storage location is the browser's localStorage and sessionStorage collections:

- `localStorage` is scoped to the browser's window. If the user reloads the page or closes and reopens the browser, the state persists. If the user opens multiple browser tabs, the state is shared across the tabs. Data persists in `localStorage` until explicitly cleared.
- `sessionStorage` is scoped to the browser tab. If the user reloads the tab, the state persists. If the user closes the tab or the browser, the state is lost. If the user opens multiple browser tabs, each tab has its own independent version of the data.

Generally, `sessionStorage` is safer to use. `sessionStorage` avoids the risk that a user opens multiple tabs and encounters the following:

- Bugs in state storage across tabs.
- Confusing behavior when a tab overwrites the state of other tabs.

`localStorage` is the better choice if the app must persist state across closing and reopening the browser.

Caveats for using browser storage:

- Similar to the use of a server-side database, loading and saving data are asynchronous.
- The requested page doesn't exist in the browser during prerendering, so local storage isn't available during prerendering.
- Storage of a few kilobytes of data is reasonable to persist for server-side Blazor apps. Beyond a few kilobytes, you must consider the performance implications because the data is loaded and saved across the network.
- Users may view or tamper with the data. ASP.NET Core Data Protection can mitigate the risk. For example, ASP.NET Core Protected Browser Storage uses ASP.NET Core Data Protection.

Third-party NuGet packages provide APIs for working with `localStorage` and `sessionStorage`. It's worth considering choosing a package that transparently uses ASP.NET Core Data Protection. Data Protection encrypts stored data and reduces the potential risk of tampering with stored data. If JSON-serialized data is stored in plain text, users can see the data using browser developer tools and also modify the stored data. Securing trivial data isn't a problem. For example, reading or modifying the stored color of a UI element isn't a significant security risk to the user or the organization. Avoid allowing users to inspect or tamper with *sensitive data*.

ASP.NET Core Protected Browser Storage

ASP.NET Core Protected Browser Storage leverages ASP.NET Core Data Protection for localStorage and sessionStorage.

> **Note**
>
> Protected Browser Storage relies on ASP.NET Core Data Protection and is only supported for server-side Blazor apps.

Save and load data within a component

In any component that requires loading or saving data to browser storage, use the @inject directive to inject an instance of either of the following:

- `ProtectedLocalStorage`
- `ProtectedSessionStorage`

The choice depends on which browser storage location you wish to use. In the following example, `sessionStorage` is used:

razor

```
@using Microsoft.AspNetCore.Components.Server.ProtectedBrowserStorage
@inject ProtectedSessionStorage ProtectedSessionStore
```

The `@using` directive can be placed in the app's `_Imports.razor` file instead of in the component. Use of the `_Imports.razor` file makes the namespace available to larger segments of the app or the whole app.

To persist the `currentCount` value in the `Counter` component of an app based on the Blazor project template, modify the `IncrementCount` method to use `ProtectedSessionStore.SetAsync`:

C#

```
private async Task IncrementCount()
{
    currentCount++;
    await ProtectedSessionStore.SetAsync("count", currentCount);
}
```

In larger, more realistic apps, storage of individual fields is an unlikely scenario. Apps are more likely to store entire model objects that include complex state.

`ProtectedSessionStore` automatically serializes and deserializes JSON data to store complex state objects.

In the preceding code example, the `currentCount` data is stored as `sessionStorage['count']` in the user's browser. The data isn't stored in plain text but rather is protected using ASP.NET Core Data Protection. The encrypted data can be inspected if `sessionStorage['count']` is evaluated in the browser's developer console.

To recover the `currentCount` data if the user returns to the `Counter` component later, including if the user is on a new circuit, use `ProtectedSessionStore.GetAsync`:

C#

```
protected override async Task OnInitializedAsync()
{
    var result = await ProtectedSessionStore.GetAsync<int>("count");
    currentCount = result.Success ? result.Value : 0;
}
```

If the component's parameters include navigation state, call `ProtectedSessionStore.GetAsync` and assign a non-`null` result in OnParametersSetAsync, not OnInitializedAsync. OnInitializedAsync is only called once when the component is first instantiated. OnInitializedAsync isn't called again later if the user navigates to a different URL while remaining on the same page. For more information, see ASP.NET Core Razor component lifecycle.

> ⚠ **Warning**
>
> The examples in this section only work if the server doesn't have prerendering enabled. With prerendering enabled, an error is generated explaining that JavaScript interop calls cannot be issued because the component is being prerendered.
>
> Either disable prerendering or add additional code to work with prerendering. To learn more about writing code that works with prerendering, see the Handle prerendering section.

Handle the loading state

Since browser storage is accessed asynchronously over a network connection, there's always a period of time before the data is loaded and available to a component. For the

best results, render a message while loading is in progress instead of displaying blank or default data.

One approach is to track whether the data is `null`, which means that the data is still loading. In the default `Counter` component, the count is held in an `int`. Make currentCount nullable by adding a question mark (`?`) to the type (`int`):

C#

```
private int? currentCount;
```

Instead of unconditionally displaying the count and **`Increment`** button, display these elements only if the data is loaded by checking HasValue:

razor

```
@if (currentCount.HasValue)
{
    <p>Current count: <strong>@currentCount</strong></p>
    <button @onclick="IncrementCount">Increment</button>
}
else
{
    <p>Loading...</p>
}
```

Handle prerendering

During prerendering:

- An interactive connection to the user's browser doesn't exist.
- The browser doesn't yet have a page in which it can run JavaScript code.

`localStorage` or `sessionStorage` aren't available during prerendering. If the component attempts to interact with storage, an error is generated explaining that JavaScript interop calls cannot be issued because the component is being prerendered.

One way to resolve the error is to disable prerendering. This is usually the best choice if the app makes heavy use of browser-based storage. Prerendering adds complexity and doesn't benefit the app because the app can't prerender any useful content until `localStorage` or `sessionStorage` are available.

To disable prerendering, indicate the render mode with the `prerender` parameter set to `false` at the highest-level component in the app's component hierarchy that isn't a root

component.

> **Note**
>
> Making a root component interactive, such as the `App` component, isn't supported. Therefore, prerendering can't be disabled directly by the `App` component.

For apps based on the Blazor Web App project template, prerendering is typically disabled where the `Routes` component is used in the `App` component (`Components/App.razor`):

razor

```
<Routes @rendermode="new InteractiveServerRenderMode(prerender: false)" />
```

Also, disable prerendering for the `HeadOutlet` component:

razor

```
<HeadOutlet @rendermode="new InteractiveServerRenderMode(prerender: false)"
/>
```

For more information, see ASP.NET Core Blazor render modes.

When prerendering is disabled, prerendering of <head> content is disabled.

Prerendering might be useful for other pages that don't use `localStorage` or `sessionStorage`. To retain prerendering, defer the loading operation until the browser is connected to the circuit. The following is an example for storing a counter value:

razor

```
@using Microsoft.AspNetCore.Components.Server.ProtectedBrowserStorage
@inject ProtectedLocalStorage ProtectedLocalStore

@if (isConnected)
{
    <p>Current count: <strong>@currentCount</strong></p>
    <button @onclick="IncrementCount">Increment</button>
}
else
{
    <p>Loading...</p>
}

@code {
```

```
    private int currentCount;
    private bool isConnected;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            isConnected = true;
            await LoadStateAsync();
            StateHasChanged();
        }
    }

    private async Task LoadStateAsync()
    {
        var result = await ProtectedLocalStore.GetAsync<int>("count");
        currentCount = result.Success ? result.Value : 0;
    }

    private async Task IncrementCount()
    {
        currentCount++;
        await ProtectedLocalStore.SetAsync("count", currentCount);
    }
}
```

Factor out the state preservation to a common location

If many components rely on browser-based storage, implementing state provider code many times creates code duplication. One option for avoiding code duplication is to create a *state provider parent component* that encapsulates the state provider logic. Child components can work with persisted data without regard to the state persistence mechanism.

In the following example of a `CounterStateProvider` component, counter data is persisted to `sessionStorage`:

razor

```
@using Microsoft.AspNetCore.Components.Server.ProtectedBrowserStorage
@inject ProtectedSessionStorage ProtectedSessionStore

@if (isLoaded)
{
    <CascadingValue Value="this">
        @ChildContent
    </CascadingValue>
}
else
{
```

```
    <p>Loading...</p>
}

@code {
    private bool isLoaded;

    [Parameter]
    public RenderFragment? ChildContent { get; set; }

    public int CurrentCount { get; set; }

    protected override async Task OnInitializedAsync()
    {
        var result = await ProtectedSessionStore.GetAsync<int>("count");
        CurrentCount = result.Success ? result.Value : 0;
        isLoaded = true;
    }

    public async Task SaveChangesAsync()
    {
        await ProtectedSessionStore.SetAsync("count", CurrentCount);
    }
}
```

> ⓘ Note
>
> For more information on RenderFragment, see ASP.NET Core Razor components.

The `CounterStateProvider` component handles the loading phase by not rendering its child content until state loading is complete.

To make the state accessible to all components in an app, wrap the `CounterStateProvider` component around the Router (`<Router>...</Router>`) in the `Routes` component with global interactive server-side rendering (interactive SSR).

In the `App` component (`Components/App.razor`):

razor

```
<Routes @rendermode="InteractiveServer" />
```

In the `Routes` component (`Components/Routes.razor`):

razor

```
<CounterStateProvider>
    <Router ...>
        ...
```

```
    </Router>
</CounterStateProvider>
```

Wrapped components receive and can modify the persisted counter state. The following `Counter` component implements the pattern:

razor

```razor
@page "/counter"

<p>Current count: <strong>@CounterStateProvider?.CurrentCount</strong></p>
<button @onclick="IncrementCount">Increment</button>

@code {
    [CascadingParameter]
    private CounterStateProvider? CounterStateProvider { get; set; }

    private async Task IncrementCount()
    {
        if (CounterStateProvider is not null)
        {
            CounterStateProvider.CurrentCount++;
            await CounterStateProvider.SaveChangesAsync();
        }
    }
}
```

The preceding component isn't required to interact with `ProtectedBrowserStorage`, nor does it deal with a "loading" phase.

To deal with prerendering as described earlier, `CounterStateProvider` can be amended so that all of the components that consume the counter data automatically work with prerendering. For more information, see the Handle prerendering section.

In general, the *state provider parent component* pattern is recommended:

- To consume state across many components.
- If there's just one top-level state object to persist.

To persist many different state objects and consume different subsets of objects in different places, it's better to avoid persisting state globally.

In-memory state container service

Nested components typically bind data using *chained bind* as described in ASP.NET Core Blazor data binding. Nested and unnested components can share access to data using a

registered in-memory state container. A custom state container class can use an assignable Action to notify components in different parts of the app of state changes. In the following example:

- A pair of components uses a state container to track a property.
- One component in the following example is nested in the other component, but nesting isn't required for this approach to work.

> **ⓘ Important**
>
> The example in this section demonstrates how to create an in-memory state container service, register the service, and use the service in components. The example doesn't persist data without further development. For persistent storage of data, the state container must adopt an underlying storage mechanism that survives when browser memory is cleared. This can be accomplished with `localStorage` / `sessionStorage` or some other technology.

`StateContainer.cs`:

C#

```
public class StateContainer
{
    private string? savedString;

    public string Property
    {
        get => savedString ?? string.Empty;
        set
        {
            savedString = value;
            NotifyStateChanged();
        }
    }

    public event Action? OnChange;

    private void NotifyStateChanged() => OnChange?.Invoke();
}
```

Client-side apps (`Program` file):

C#

```
builder.Services.AddSingleton<StateContainer>();
```

Server-side apps (`Program` file, ASP.NET Core in .NET 6 or later):

C#

```
builder.Services.AddScoped<StateContainer>();
```

Server-side apps (`Startup.ConfigureServices` of `Startup.cs`, ASP.NET Core earlier than 6.0):

C#

```
services.AddScoped<StateContainer>();
```

`Shared/Nested.razor`:

razor

```
@implements IDisposable
@inject StateContainer StateContainer

<h2>Nested component</h2>

<p>Nested component Property: <b>@StateContainer.Property</b></p>

<p>
    <button @onclick="ChangePropertyValue">
        Change the Property from the Nested component
    </button>
</p>

@code {
    protected override void OnInitialized()
    {
        StateContainer.OnChange += StateHasChanged;
    }

    private void ChangePropertyValue()
    {
        StateContainer.Property =
            $"New value set in the Nested component: {DateTime.Now}";
    }

    public void Dispose()
    {
        StateContainer.OnChange -= StateHasChanged;
    }
}
```

`StateContainerExample.razor`:

razor

```razor
@page "/state-container-example"
@implements IDisposable
@inject StateContainer StateContainer

<h1>State Container Example component</h1>

<p>State Container component Property: <b>@StateContainer.Property</b></p>

<p>
    <button @onclick="ChangePropertyValue">
        Change the Property from the State Container Example component
    </button>
</p>

<Nested />

@code {
    protected override void OnInitialized()
    {
        StateContainer.OnChange += StateHasChanged;
    }

    private void ChangePropertyValue()
    {
        StateContainer.Property = "New value set in the State " +
            $"Container Example component: {DateTime.Now}";
    }

    public void Dispose()
    {
        StateContainer.OnChange -= StateHasChanged;
    }
}
```

The preceding components implement IDisposable, and the `OnChange` delegates are unsubscribed in the `Dispose` methods, which are called by the framework when the components are disposed. For more information, see ASP.NET Core Razor component lifecycle.

Additional approaches

When implementing custom state storage, a useful approach is to adopt cascading values and parameters:

- To consume state across many components.
- If there's just one top-level state object to persist.

Troubleshoot

In a custom state management service, a callback invoked outside of Blazor's synchronization context must wrap the logic of the callback in ComponentBase.InvokeAsync to move it onto the renderer's synchronization context.

When the state management service doesn't call StateHasChanged on Blazor's synchronization context, the following error is thrown:

> System.InvalidOperationException: 'The current thread is not associated with the Dispatcher. Use InvokeAsync() to switch execution to the Dispatcher when triggering rendering or component state.'

For more information and an example of how to address this error, see ASP.NET Core Razor component rendering.

Additional resources

- Save app state before an authentication operation (Blazor WebAssembly)
- Managing state via an external server API
  - Call a web API from an ASP.NET Core Blazor app

Debug ASP.NET Core apps

Article • 10/21/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article describes how to debug Blazor apps, including debugging Blazor WebAssembly apps with browser developer tools or an integrated development environment (IDE).

Blazor Web Apps can be debugged in Visual Studio or Visual Studio Code.

Blazor WebAssembly apps can be debugged:

- In Visual Studio or Visual Studio Code.
- Using browser developer tools in Chromium-based browsers, including Microsoft Edge, Google Chrome, and Firefox.

Available scenarios for Blazor WebAssembly debugging include:

- Set and remove breakpoints.
- Run the app with debugging support in IDEs.
- Single-step through the code.
- Resume code execution with a keyboard shortcut in IDEs.
- In the *Locals* window, observe the values of local variables.
- See the call stack, including call chains between JavaScript and .NET.
- Use a symbol server for debugging, configured by Visual Studio preferences.

Unsupported scenarios include:

- Debug in non-local scenarios (for example, Windows Subsystem for Linux (WSL) or Visual Studio Codespaces).
- Debug in Firefox from Visual Studio or Visual Studio Code.

Prerequisites

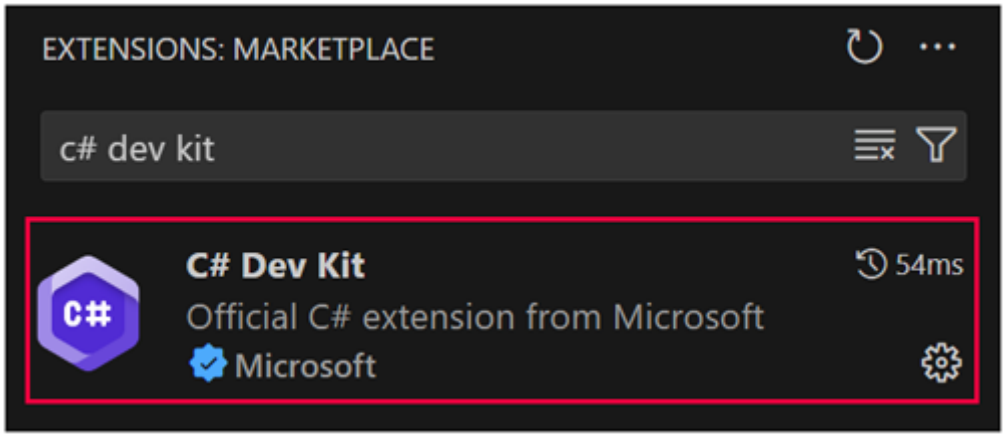
This section explains the prerequisites for debugging.

Browser prerequisites

The latest version of the following browsers:

- Google Chrome
- Microsoft Edge
- Firefox (browser developer tools only)

Ensure that firewalls or proxies don't block communication with the debug proxy (`NodeJS` process). For more information, see the Firewall configuration section.



> **Note**
>
> Apple Safari on macOS isn't currently supported.

IDE prerequisites

The latest version of Visual Studio or Visual Studio Code is required.

Visual Studio Code prerequisites

Visual Studio Code requires the C# Dev Kit for Visual Studio Code (Getting Started with C# in VS Code). In the Visual Studio Code Extensions Marketplace, filter the extension list with "`c# dev kit`" to locate the extension:

Installing the C# Dev Kit automatically installs the following additional extensions:

- .NET Install Tool
- C#
- IntelliCode for C# Dev Kit

If you encounter warnings or errors, you can open an issue (microsoft/vscode-dotnettools GitHub repository) describing the problem.

App configuration prerequisites

The guidance in this subsection applies to client-side debugging.

Open the `Properties/launchSettings.json` file of the startup project. Confirm the presence of the following `inspectUri` property in each launch profile of the file's `profiles` node. If the following property isn't present, add it to each profile:

JSON

```
"inspectUri": "{wsProtocol}://{url.hostname}:{url.port}/_framework/debug/ws-proxy?browser={browserInspectUri}"
```

The `inspectUri` property:

- Enables the IDE to detect that the app is a Blazor app.
- Instructs the script debugging infrastructure to connect to the browser through Blazor's debugging proxy.

The placeholder values for the WebSocket protocol (`wsProtocol`), host (`url.hostname`), port (`url.port`), and inspector URI on the launched browser (`browserInspectUri`) are provided by the framework.

Packages

Blazor Web Apps: Microsoft.AspNetCore.Components.WebAssembly.Server: References an internal package (Microsoft.NETCore.BrowserDebugHost.Transport) for assemblies that share the browser debug host.

Standalone Blazor WebAssembly: Microsoft.AspNetCore.Components.WebAssembly.DevServer: Development server for use when building Blazor apps. Calls UseWebAssemblyDebugging internally to add middleware for debugging Blazor WebAssembly apps inside Chromium developer tools.

> **Note**

For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Debug a Blazor Web App in an IDE

Visual Studio

The example in this section assumes that you've created a Blazor Web App with an interactive render mode of Auto (Server and WebAssembly) and per-component interactivity location.

1. Open the app.
2. Set a breakpoint on the `currentCount++;` line in the `Counter` component (`Pages/Counter.razor`) of the client project (`.Client`).
3. With the server project selected in **Solution Explorer**, press `F5` to run the app in the debugger.
4. In the browser, navigate to `Counter` page at `/counter`. Wait a few seconds for the debug proxy to load and run. Select the **Click me** button to hit the breakpoint.
5. In Visual Studio, inspect the value of the `currentCount` field in the **Locals** window.
6. Press `F5` to continue execution.

Breakpoints can also be hit in the server project in statically-rendered and interactively-rendered server-side components.

1. Stop the debugger.
2. In the server app, open the statically-rendered `Weather` component (`Components/Pages/Weather.razor`) and set a breakpoint anywhere in the `OnInitializedAsync` method.
3. Press `F5` to run the app in the debugger.
4. In the browser, navigate to the `Weather` page at `/weather`. Wait a few seconds for the debug proxy to load and run. Application execution stops at the breakpoint.
5. Press `F5` to continue execution.

Breakpoints are **not** hit during app startup before the debug proxy is running. This includes breakpoints in the `Program` file and breakpoints in the OnInitialized{Async}

lifecycle methods of components that are loaded by the first page requested from the app.

Debug a Blazor WebAssembly app in an IDE

Visual Studio

1. Open the app.
2. Set a breakpoint on the `currentCount++;` line in the `Counter` component (`Pages/Counter.razor`).
3. Press `F5` to run the app in the debugger.
4. In the browser, navigate to `Counter` page at `/counter`. Wait a few seconds for the debug proxy to load and run. Select the **Click me** button to hit the breakpoint.
5. In Visual Studio, inspect the value of the `currentCount` field in the **Locals** window.
6. Press `F5` to continue execution.

Breakpoints are **not** hit during app startup before the debug proxy is running. This includes breakpoints in the `Program` file and breakpoints in the OnInitialized{Async} lifecycle methods of components that are loaded by the first page requested from the app.

Attach to an existing Visual Studio Code debugging session

To attach to a running Blazor app, open the `.vscode/launch.json` file and replace the `{URL}` placeholder with the URL where the app is running:

JSON

```
{
  "name": "Attach and Debug",
  "type": "blazorwasm",
  "request": "attach",
  "url": "{URL}"
}
```

Visual Studio Code launch options

The launch configuration options in the following table are supported for the `blazorwasm` debug type (`.vscode/launch.json`).

Expand table

Option	Description
`browser`	The browser to launch for the debugging session. Set to `edge` or `chrome`. Defaults to `edge`.
`cwd`	The working directory to launch the app under.
`request`	Use `launch` to launch and attach a debugging session to a Blazor WebAssembly app or `attach` to attach a debugging session to an already-running app.
`timeout`	The number of milliseconds to wait for the debugging session to attach. Defaults to 30,000 milliseconds (30 seconds).
`trace`	Used to generate logs from the JS debugger. Set to `true` to generate logs.
`url`	The URL to open in the browser when debugging.
`webRoot`	Specifies the absolute path of the web server. Should be set if an app is served from a sub-route.

Debug Blazor WebAssembly with Google Chrome or Microsoft Edge

The guidance in this section applies debugging Blazor WebAssembly apps in:

- ***Google Chrome** running on Windows or macOS.*
- *__Microsoft Edge__ running on Windows.*

1. Run the app in a command shell with `dotnet watch` (or `dotnet run`).

2. Launch a browser and navigate to the app's URL.

3. Start remote debugging by pressing:

   - `Shift`+`Alt`+`d` on Windows.
   - `Shift`+`⌘`+`d` on macOS.

   The browser must be running with remote debugging enabled, which isn't the default. If remote debugging is disabled, an **Unable to find debuggable browser**

tab error page is rendered with instructions for launching the browser with the debugging port open. Follow the instructions for your browser.

After following the instructions to enable remote debugging, the app opens in a new browser window. Start remote debugging by pressing the HotKey combination in the new browser window:

- `Shift`+`Alt`+`d` on Windows.
- `Shift`+`⌘`+`d` on macOS.

A new window developer tools browser tab opens showing a ghosted image of the app.

> **Note**
>
> If you followed the instructions to open a new browser tab with remote debugging enabled, you can close the original browser window, leaving the second window open with the first tab running the app and the second tab running the debugger.

4. After a moment, the **Sources** tab shows a list of the app's .NET assemblies and pages.

5. Open the `file://` node. In component code (`.razor` files) and C# code files (`.cs`), breakpoints that you set are hit when code executes in the app's browser tab (the initial tab opened after starting remote debugging). After a breakpoint is hit, single-step (`F10`) through the code or resume (`F8`) code execution normally in the debugging tab.

For Chromium-based browser debugging, Blazor provides a debugging proxy that implements the Chrome DevTools Protocol and augments the protocol with .NET-specific information. When debugging keyboard shortcut is pressed, Blazor points the Chrome DevTools at the proxy. The proxy connects to the browser window you're seeking to debug (hence the need to enable remote debugging).

Debug a Blazor WebAssembly app with Firefox

The guidance in this section applies debugging Blazor WebAssembly apps in Firefox running on Windows.

Debugging a Blazor WebAssembly app with Firefox requires configuring the browser for remote debugging and connecting to the browser using the browser developer tools

through the .NET WebAssembly debugging proxy.

> **Note**
>
> Debugging in Firefox from Visual Studio isn't supported at this time.

To debug a Blazor WebAssembly app in Firefox during development:

1. Configure Firefox:
   - Open `about:config` in a new browser tab. Read and dismiss the warning that appears.
   - Enable `devtools.debugger.remote-enabled` by setting its value to `True`.
   - Enable `devtools.chrome.enabled` by setting its value to `True`.
   - Disable `devtools.debugger.prompt-connection` by setting its value to `False`.
2. Close all Firefox instances.
3. Run the app in a command shell with `dotnet watch` (or `dotnet run`).
4. Relaunch the Firefox browser and navigate to the app.
5. Open `about:debugging` in a new browser tab. **Leave this tab open**.
6. Go back to the tab where the app is running. Start remote debugging by pressing `Shift`+`Alt`+`d`.
7. In the `Debugger` tab, open the app source file you wish to debug under the `file://` node and set a breakpoint. For example, set a breakpoint on the `currentCount++;` line in the `IncrementCount` method of the `Counter` component (`Pages/Counter.razor`).
8. Navigate to the `Counter` component page (`/counter`) in the app's browser tab and select the counter button to hit the breakpoint.
9. Press `F5` to continue execution in the debugging tab.

Break on unhandled exceptions

The debugger doesn't break on unhandled exceptions because Blazor catches exceptions that are unhandled by developer code.

To break on unhandled exceptions:

- Open the debugger's exception settings (**Debug** > **Windows** > **Exception Settings**) in Visual Studio.
- Set the following **JavaScript Exceptions** settings:
  - **All Exceptions**

- **Uncaught Exceptions**

Browser source maps

Browser source maps allow the browser to map compiled files back to their original source files and are commonly used for client-side debugging. However, Blazor doesn't currently map C# directly to JavaScript/WASM. Instead, Blazor does IL interpretation within the browser, so source maps aren't relevant.

Firewall configuration

If a firewall blocks communication with the debug proxy, create a firewall exception rule that permits communication between the browser and the `NodeJS` process.

> ⚠ **Warning**
>
> Modification of a firewall configuration must be made with care to avoid creating security vulnerabilities. Carefully apply security guidance, follow best security practices, and respect warnings issued by the firewall's manufacturer.
>
> Permitting open communication with the `NodeJS` process:
>
> - Opens up the Node server to any connection, depending on the firewall's capabilities and configuration.
> - Might be risky depending on your network.
> - **Is only recommended on developer machines.**
>
> If possible, only allow open communication with the `NodeJS` process **on trusted or private networks**.

For Windows Firewall configuration guidance, see Create an Inbound Program or Service Rule. For more information, see Windows Defender Firewall with Advanced Security and related articles in the Windows Firewall documentation set.

Troubleshoot

If you're running into errors, the following tips may help:

- Remove breakpoints:

    - Google Chrome: In the **Debugger** tab, open the developer tools in your browser. In the console, execute `localStorage.clear()` to remove any breakpoints.
    - Microsoft Edge: In the **Application** tab, open **Local storage**. Right-click the site and select **Clear**.
- Confirm that you've installed and trusted the ASP.NET Core HTTPS development certificate. For more information, see Enforce HTTPS in ASP.NET Core.
- Visual Studio requires the **Enable JavaScript debugging for ASP.NET (Chrome and Edge)** option in **Tools** > **Options** > **Debugging** > **General**. This is the default setting for Visual Studio. If debugging isn't working, confirm that the option is selected.
- If your environment uses an HTTP proxy, make sure that `localhost` is included in the proxy bypass settings. This can be done by setting the `NO_PROXY` environment variable in either:
    - The `launchSettings.json` file for the project.
    - At the user or system environment variables level for it to apply to all apps. When using an environment variable, restart Visual Studio for the change to take effect.
- Ensure that firewalls or proxies don't block communication with the debug proxy (`NodeJS` process). For more information, see the Firewall configuration section.

Breakpoints in `OnInitialized{Async}` not hit

The Blazor framework's debugging proxy doesn't launch instantly on app startup, so breakpoints in the OnInitialized{Async} lifecycle methods might not be hit. We recommend adding a delay at the start of the method body to give the debug proxy some time to launch before the breakpoint is hit. You can include the delay based on an if compiler directive to ensure that the delay isn't present for a release build of the app.

OnInitialized:

C#

```
protected override void OnInitialized()
{
#if DEBUG
    Thread.Sleep(10000);
#endif

    ...
}
```

OnInitializedAsync:

C#

```
protected override async Task OnInitializedAsync()
{
#if DEBUG
    await Task.Delay(10000);
#endif

    ...
}
```

Visual Studio (Windows) timeout

If Visual Studio throws an exception that the debug adapter failed to launch mentioning that the timeout was reached, you can adjust the timeout with a Registry setting:

Console

```
VsRegEdit.exe set "<VSInstallFolder>" HKCU JSDebugger\Options\Debugging
"BlazorTimeoutInMilliseconds" dword {TIMEOUT}
```

The `{TIMEOUT}` placeholder in the preceding command is in milliseconds. For example, one minute is assigned as `60000`.

Lazy load assemblies in ASP.NET Core Blazor WebAssembly

Article • 02/22/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Blazor WebAssembly app startup performance can be improved by waiting to load developer-created app assemblies until the assemblies are required, which is called *lazy loading*.

This article's initial sections cover the app configuration. For a working demonstration, see the Complete example section at the end of this article.

This article only applies to Blazor WebAssembly apps. Assembly lazy loading doesn't benefit server-side apps because server-rendered apps don't download assemblies to the client.

Lazy loading shouldn't be used for core runtime assemblies, which might be trimmed on publish and unavailable on the client when the app loads.

File extension placeholder (`{FILE EXTENSION}`) for assembly files

Assembly files use the Webcil packaging format for .NET assemblies with a `.wasm` file extension.

Throughout the article, the `{FILE EXTENSION}` placeholder represents "`wasm`".

Project file configuration

Mark assemblies for lazy loading in the app's project file (`.csproj`) using the `BlazorWebAssemblyLazyLoad` item. Use the assembly name with file extension. The Blazor framework prevents the assembly from loading at app launch.

XML

```xml
<ItemGroup>
  <BlazorWebAssemblyLazyLoad Include="{ASSEMBLY NAME}.{FILE EXTENSION}" />
</ItemGroup>
```

The `{ASSEMBLY NAME}` placeholder is the name of the assembly, and the `{FILE EXTENSION}` placeholder is the file extension. The file extension is required.

Include one `BlazorWebAssemblyLazyLoad` item for each assembly. If an assembly has dependencies, include a `BlazorWebAssemblyLazyLoad` entry for each dependency.

`Router` component configuration

The Blazor framework automatically registers a singleton service for lazy loading assemblies in client-side Blazor WebAssembly apps, LazyAssemblyLoader. The LazyAssemblyLoader.LoadAssembliesAsync method:

- Uses JS interop to fetch assemblies via a network call.
- Loads assemblies into the runtime executing on WebAssembly in the browser.

Blazor's Router component designates the assemblies that Blazor searches for routable components and is also responsible for rendering the component for the route where the user navigates. The Router component's OnNavigateAsync method is used in conjunction with lazy loading to load the correct assemblies for endpoints that a user requests.

Logic is implemented inside OnNavigateAsync to determine the assemblies to load with LazyAssemblyLoader. Options for how to structure the logic include:

- Conditional checks inside the OnNavigateAsync method.
- A lookup table that maps routes to assembly names, either injected into the component or implemented within the @code block.

In the following example:

- The namespace for Microsoft.AspNetCore.Components.WebAssembly.Services is specified.
- The LazyAssemblyLoader service is injected (`AssemblyLoader`).
- The `{PATH}` placeholder is the path where the list of assemblies should load. The example uses a conditional check for a single path that loads a single set of assemblies.

- The `{LIST OF ASSEMBLIES}` placeholder is the comma-separated list of assembly file name strings, including their file extensions (for example, `"Assembly1.{FILE EXTENSION}", "Assembly2.{FILE EXTENSION}"`).

`App.razor`:

razor

```
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.WebAssembly.Services
@using Microsoft.Extensions.Logging
@inject LazyAssemblyLoader AssemblyLoader
@inject ILogger<App> Logger

<Router AppAssembly="typeof(App).Assembly"
    OnNavigateAsync="OnNavigateAsync">
    ...
</Router>

@code {
    private async Task OnNavigateAsync(NavigationContext args)
    {
        try
           {
               if (args.Path == "{PATH}")
               {
                   var assemblies = await
AssemblyLoader.LoadAssembliesAsync(
                           new[] { {LIST OF ASSEMBLIES} });
               }
           }
           catch (Exception ex)
           {
               Logger.LogError("Error: {Message}", ex.Message);
           }
    }
}
```

> **Note**
>
> The preceding example doesn't show the contents of the Router component's Razor markup (`...`). For a demonstration with complete code, see the Complete example section of this article.

Assemblies that include routable components

When the list of assemblies includes routable components, the assembly list for a given path is passed to the Router component's AdditionalAssemblies collection.

In the following example:

- The List<Assembly> in `lazyLoadedAssemblies` passes the assembly list to AdditionalAssemblies. The framework searches the assemblies for routes and updates the route collection if new routes are found. To access the Assembly type, the namespace for System.Reflection is included at the top of the `App.razor` file.
- The `{PATH}` placeholder is the path where the list of assemblies should load. The example uses a conditional check for a single path that loads a single set of assemblies.
- The `{LIST OF ASSEMBLIES}` placeholder is the comma-separated list of assembly file name strings, including their file extensions (for example, `"Assembly1.{FILE EXTENSION}", "Assembly2.{FILE EXTENSION}"`).

`App.razor`:

razor

```
@using System.Reflection
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.WebAssembly.Services
@using Microsoft.Extensions.Logging
@inject ILogger<App> Logger
@inject LazyAssemblyLoader AssemblyLoader

<Router AppAssembly="typeof(App).Assembly"
    AdditionalAssemblies="lazyLoadedAssemblies"
    OnNavigateAsync="OnNavigateAsync">
    ...
</Router>

@code {
    private List<Assembly> lazyLoadedAssemblies = new();

    private async Task OnNavigateAsync(NavigationContext args)
    {
        try
           {
               if (args.Path == "{PATH}")
               {
                   var assemblies = await
AssemblyLoader.LoadAssembliesAsync(
                       new[] { {LIST OF ASSEMBLIES} });
                   lazyLoadedAssemblies.AddRange(assemblies);
               }
           }
           catch (Exception ex)
```

```
            {
                Logger.LogError("Error: {Message}", ex.Message);
            }
    }
}
```

> **Note**
>
> The preceding example doesn't show the contents of the Router component's Razor markup (`...`). For a demonstration with complete code, see the Complete example section of this article.

For more information, see ASP.NET Core Blazor routing and navigation.

User interaction with `<Navigating>` content

While loading assemblies, which can take several seconds, the Router component can indicate to the user that a page transition is occurring with the router's Navigating property.

For more information, see ASP.NET Core Blazor routing and navigation.

Handle cancellations in `OnNavigateAsync`

The NavigationContext object passed to the OnNavigateAsync callback contains a CancellationToken that's set when a new navigation event occurs. The OnNavigateAsync callback must throw when the cancellation token is set to avoid continuing to run the OnNavigateAsync callback on an outdated navigation.

For more information, see ASP.NET Core Blazor routing and navigation.

`OnNavigateAsync` events and renamed assembly files

The resource loader relies on the assembly names that are defined in the `blazor.boot.json` file. If assemblies are renamed, the assembly names used in an OnNavigateAsync callback and the assembly names in the `blazor.boot.json` file are out of sync.

To rectify this:

- Check to see if the app is running in the `Production` environment when determining which assembly names to use.
- Store the renamed assembly names in a separate file and read from that file to determine what assembly name to use with the LazyAssemblyLoader service and OnNavigateAsync callback.

Complete example

The demonstration in this section:

- Creates a robot controls assembly (`GrantImaharaRobotControls.{FILE EXTENSION}`) as a Razor class library (RCL) that includes a `Robot` component (`Robot.razor` with a route template of `/robot`).
- Lazily loads the RCL's assembly to render its `Robot` component when the `/robot` URL is requested by the user.

Create a standalone Blazor WebAssembly app to demonstrate lazy loading of a Razor class library's assembly. Name the project `LazyLoadTest`.

Add an ASP.NET Core class library project to the solution:

- Visual Studio: Right-click the solution file in **Solution Explorer** and select **Add** > **New project**. From the dialog of new project types, select **Razor Class Library**. Name the project `GrantImaharaRobotControls`. Do **not** select the **Support pages and view** checkbox.
- Visual Studio Code/.NET CLI: Execute `dotnet new razorclasslib -o GrantImaharaRobotControls` from a command prompt. The `-o|--output` option creates a folder and names the project `GrantImaharaRobotControls`.

The example component presented later in this section uses a Blazor form. In the RCL project, add the Microsoft.AspNetCore.Components.Forms package to the project.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

Create a `HandGesture` class in the RCL with a `ThumbUp` method that hypothetically makes a robot perform a thumbs-up gesture. The method accepts an argument for the axis, `Left` or `Right`, as an enum. The method returns `true` on success.

`HandGesture.cs`:

```C#
using Microsoft.Extensions.Logging;

namespace GrantImaharaRobotControls;

public static class HandGesture
{
    public static bool ThumbUp(Axis axis, ILogger logger)
    {
        logger.LogInformation("Thumb up gesture. Axis: {Axis}", axis);

        // Code to make robot perform gesture

        return true;
    }
}

public enum Axis { Left, Right }
```

Add the following component to the root of the RCL project. The component permits the user to submit a left or right hand thumb-up gesture request.

`Robot.razor`:

```razor
@page "/robot"
@using Microsoft.AspNetCore.Components.Forms
@using Microsoft.Extensions.Logging
@inject ILogger<Robot> Logger

<h1>Robot</h1>

<EditForm FormName="RobotForm" Model="robotModel"
OnValidSubmit="HandleValidSubmit">
    <InputRadioGroup @bind-Value="robotModel.AxisSelection">
        @foreach (var entry in Enum.GetValues<Axis>())
        {
            <InputRadio Value="entry" />
            <text> </text>@entry<br>
        }
    </InputRadioGroup>

    <button type="submit">Submit</button>
</EditForm>

<p>
    @message
</p>
```

```
@code {
    private RobotModel robotModel = new() { AxisSelection = Axis.Left };
    private string? message;

    private void HandleValidSubmit()
    {
        Logger.LogInformation("HandleValidSubmit called");

        var result = HandGesture.ThumbUp(robotModel.AxisSelection, Logger);

        message = $"ThumbUp returned {result} at {DateTime.Now}.";
    }

    public class RobotModel
    {
        public Axis AxisSelection { get; set; }
    }
}
```

In the `LazyLoadTest` project, create a project reference for the `GrantImaharaRobotControls` RCL:

- Visual Studio: Right-click the `LazyLoadTest` project and select **Add** > **Project Reference** to add a project reference for the `GrantImaharaRobotControls` RCL.
- Visual Studio Code/.NET CLI: Execute `dotnet add reference {PATH}` in a command shell from the project's folder. The `{PATH}` placeholder is the path to the RCL project.

Specify the RCL's assembly for lazy loading in the `LazyLoadTest` app's project file (`.csproj`):

XML

```
<ItemGroup>
    <BlazorWebAssemblyLazyLoad Include="GrantImaharaRobotControls.{FILE
EXTENSION}" />
</ItemGroup>
```

The following Router component demonstrates loading the `GrantImaharaRobotControls.{FILE EXTENSION}` assembly when the user navigates to `/robot`. Replace the app's default `App` component with the following `App` component.

During page transitions, a styled message is displayed to the user with the `<Navigating>` element. For more information, see the User interaction with <Navigating> content section.

The assembly is assigned to AdditionalAssemblies, which results in the router searching the assembly for routable components, where it finds the `Robot` component. The `Robot` component's route is added to the app's route collection. For more information, see the ASP.NET Core Blazor routing and navigation article and the Assemblies that include routable components section of this article.

`App.razor`:

razor

```
@using System.Reflection
@using Microsoft.AspNetCore.Components.Routing
@using Microsoft.AspNetCore.Components.WebAssembly.Services
@using Microsoft.Extensions.Logging
@inject ILogger<App> Logger
@inject LazyAssemblyLoader AssemblyLoader

<Router AppAssembly="typeof(App).Assembly"
        AdditionalAssemblies="lazyLoadedAssemblies"
        OnNavigateAsync="OnNavigateAsync">
    <Navigating>
        <div style="padding:20px;background-color:blue;color:white">
            <p>Loading the requested page&hellip;</p>
        </div>
    </Navigating>
    <Found Context="routeData">
        <RouteView RouteData="routeData" DefaultLayout="typeof(MainLayout)"
/>
    </Found>
    <NotFound>
        <LayoutView Layout="typeof(MainLayout)">
            <p>Sorry, there's nothing at this address.</p>
        </LayoutView>
    </NotFound>
</Router>

@code {
    private List<Assembly> lazyLoadedAssemblies = new();

    private async Task OnNavigateAsync(NavigationContext args)
    {
        try
        {
            if (args.Path == "robot")
            {
                var assemblies = await AssemblyLoader.LoadAssembliesAsync(
                    new[] { "GrantImaharaRobotControls.{FILE EXTENSION}" });
                lazyLoadedAssemblies.AddRange(assemblies);
            }
        }
        catch (Exception ex)
        {
```

```
            Logger.LogError("Error: {Message}", ex.Message);
        }
    }
}
```

Build and run the app.

When the `Robot` component from the RCL is requested at `/robot`, the `GrantImaharaRobotControls.{FILE EXTENSION}` assembly is loaded and the `Robot` component is rendered. You can inspect the assembly loading in the **Network** tab of the browser's developer tools.

Troubleshoot

- If unexpected rendering occurs, such as rendering a component from a previous navigation, confirm that the code throws if the cancellation token is set.
- If assemblies configured for lazy loading unexpectedly load at app start, check that the assembly is marked for lazy loading in the project file.

Additional resources

- Handle asynchronous navigation events with OnNavigateAsync
- ASP.NET Core Blazor performance best practices

ASP.NET Core Blazor WebAssembly native dependencies

Article • 04/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Blazor WebAssembly apps can use native dependencies built to run on WebAssembly. You can statically link native dependencies into the .NET WebAssembly runtime using the **.NET WebAssembly build tools**, the same tools used to ahead-of-time (AOT) compile a Blazor app to WebAssembly and to relink the runtime to remove unused features.

This article only applies to Blazor WebAssembly.

.NET WebAssembly build tools

The .NET WebAssembly build tools are based on Emscripten, a compiler toolchain for the web platform. For more information on the build tools, including installation, see ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation.

Add native dependencies to a Blazor WebAssembly app by adding `NativeFileReference` items in the app's project file. When the project is built, each `NativeFileReference` is passed to Emscripten by the .NET WebAssembly build tools so that they are compiled and linked into the runtime. Next, p/invoke into the native code from the app's .NET code.

Generally, any portable native code can be used as a native dependency with Blazor WebAssembly. You can add native dependencies to C/C++ code or code previously compiled using Emscripten:

- Object files (`.o`)
- Archive files (`.a`)
- Bitcode (`.bc`)

- Standalone WebAssembly modules (`.wasm`)

Prebuilt dependencies typically must be built using the same version of Emscripten used to build the .NET WebAssembly runtime.

> **Note**
>
> For Mono /WebAssembly MSBuild properties and targets, see WasmApp.targets (dotnet/runtime GitHub repository). Official documentation for common MSBuild properties is planned per Document blazor msbuild configuration options (dotnet/docs #27395).

Use native code

Add a simple native C function to a Blazor WebAssembly app:

1. Create a new Blazor WebAssembly project.
2. Add a `Test.c` file to the project.
3. Add a C function for computing factorials.

   `Test.c`:

   C

   ```
   int fact(int n)
   {
       if (n == 0) return 1;
       return n * fact(n - 1);
   }
   ```

4. Add a `NativeFileReference` for `Test.c` in the app's project file:

   XML

   ```
   <ItemGroup>
     <NativeFileReference Include="Test.c" />
   </ItemGroup>
   ```

5. In a Razor component, add a DllImportAttribute for the `fact` function in the generated `Test` library and call the `fact` method from .NET code in the component.

`Pages/NativeCTest.razor`:

razor

```razor
@page "/native-c-test"
@using System.Runtime.InteropServices

<PageTitle>Native C</PageTitle>

<h1>Native C Test</h1>

<p>
    @@fact(3) result: @fact(3)
</p>

@code {
    [DllImport("Test")]
    static extern int fact(int n);
}
```

When you build the app with the .NET WebAssembly build tools installed, the native C code is compiled and linked into the .NET WebAssembly runtime (`dotnet.wasm`). After the app is built, run the app to see the rendered factorial value.

C++ managed method callbacks

Label managed methods that are passed to C++ with the `[UnmanagedCallersOnly]` attribute.

The method marked with the `[UnmanagedCallersOnly]` attribute must be `static`. To call an instance method in a Razor component, pass a `GCHandle` for the instance to C++ and then pass it back to native. Alternatively, use some other method to identify the instance of the component.

The method marked with `[DllImport]` must use a C# 9.0 function pointer rather than a delegate type for the callback argument.

> ⓘ Note
>
> For C# function pointer types in `[DllImport]` methods, use `IntPtr` in the method signature on the managed side instead of `delegate *unmanaged<int, void>`. For more information, see [[WASM] callback from native code to .NET: Parsing function pointer types in signatures is not supported (dotnet/runtime #56145)].

Package native dependencies in a NuGet package

NuGet packages can contain native dependencies for use on WebAssembly. These libraries and their native functionality are then available to any Blazor WebAssembly app. The files for the native dependencies should be built for WebAssembly and packaged in the `browser-wasm` architecture-specific folder. WebAssembly-specific dependencies aren't referenced automatically and must be referenced manually as `NativeFileReference`s. Package authors can choose to add the native references by including a `.props` file in the package with the references.

SkiaSharp example library use

SkiaSharp is a cross-platform 2D graphics library for .NET based on the native Skia graphics library with support for Blazor WebAssembly.

To use SkiaSharp in a Blazor WebAssembly app:

1. Add a package reference to the SkiaSharp.Views.Blazor package in a Blazor WebAssembly project. Use Visual Studio's process for adding packages to an app (**Manage NuGet Packages** with **Include prerelease** selected) or execute the dotnet add package command in a command shell:

   .NET CLI

   ```
   dotnet add package --prerelease SkiaSharp.Views.Blazor
   ```

   > **Note**
   >
   > For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

2. Add a `SKCanvasView` component to the app with the following:

   - `SkiaSharp` and `SkiaSharp.Views.Blazor` namespaces.
   - Logic to draw in the SkiaSharp Canvas View component (`SKCanvasView`).

   `Pages/NativeDependencyExample.razor`:

   razor

```
@page "/native-dependency-example"
@using SkiaSharp
@using SkiaSharp.Views.Blazor

<PageTitle>Native dependency</PageTitle>

<h1>Native dependency example with SkiaSharp</h1>

<SKCanvasView OnPaintSurface="OnPaintSurface" />

@code {
    private void OnPaintSurface(SKPaintSurfaceEventArgs e)
    {
        var canvas = e.Surface.Canvas;

        canvas.Clear(SKColors.White);

        using var paint = new SKPaint
        {
            Color = SKColors.Black,
            IsAntialias = true,
            TextSize = 24
        };

        canvas.DrawText("SkiaSharp", 0, 24, paint);
    }
}
```

3. Build the app, which might take several minutes. Run the app and navigate to the `NativeDependencyExample` component at `/native-dependency-example`.

ASP.NET Core Blazor performance best practices

Article • 09/12/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Blazor is optimized for high performance in most realistic application UI scenarios. However, the best performance depends on developers adopting the correct patterns and features.

> **Note**
>
> The code examples in this article adopt nullable reference types (NRTs) and .NET compiler null-state static analysis, which are supported in ASP.NET Core in .NET 6 or later.

Optimize rendering speed

Optimize rendering speed to minimize rendering workload and improve UI responsiveness, which can yield a *ten-fold or higher improvement* in UI rendering speed.

Avoid unnecessary rendering of component subtrees

You might be able to remove the majority of a parent component's rendering cost by skipping the rerendering of child component subtrees when an event occurs. You should only be concerned about skipping the rerendering subtrees that are particularly expensive to render and are causing UI lag.

At runtime, components exist in a hierarchy. A root component (the first component loaded) has child components. In turn, the root's children have their own child components, and so on. When an event occurs, such as a user selecting a button, the following process determines which components to rerender:

1. The event is dispatched to the component that rendered the event's handler. After executing the event handler, the component is rerendered.
2. When a component is rerendered, it supplies a new copy of parameter values to each of its child components.
3. After a new set of parameter values is received, each component decides whether to rerender. Components rerender if the parameter values may have changed, for example, if they're mutable objects.

The last two steps of the preceding sequence continue recursively down the component hierarchy. In many cases, the entire subtree is rerendered. Events targeting high-level components can cause expensive rerendering because every component below the high-level component must rerender.

To prevent rendering recursion into a particular subtree, use either of the following approaches:

- Ensure that child component parameters are of primitive immutable types, such as `string`, `int`, `bool`, `DateTime`, and other similar types. The built-in logic for detecting changes automatically skips rerendering if the primitive immutable parameter values haven't changed. If you render a child component with `<Customer CustomerId="item.CustomerId" />`, where `CustomerId` is an `int` type, then the `Customer` component isn't rerendered unless `item.CustomerId` changes.
- Override ShouldRender:
  - To accept nonprimitive parameter values, such as complex custom model types, event callbacks, or RenderFragment values.
  - If authoring a UI-only component that doesn't change after the initial render, regardless of parameter value changes.

The following airline flight search tool example uses private fields to track the necessary information to detect changes. The previous inbound flight identifier (`prevInboundFlightId`) and previous outbound flight identifier (`prevOutboundFlightId`) track information for the next potential component update. If either of the flight identifiers change when the component's parameters are set in OnParametersSet, the component is rerendered because `shouldRender` is set to `true`. If `shouldRender` evaluates to `false` after checking the flight identifiers, an expensive rerender is avoided:

razor

```
@code {
    private int prevInboundFlightId = 0;
    private int prevOutboundFlightId = 0;
    private bool shouldRender;
```

```
    [Parameter]
    public FlightInfo? InboundFlight { get; set; }

    [Parameter]
    public FlightInfo? OutboundFlight { get; set; }

    protected override void OnParametersSet()
    {
        shouldRender = InboundFlight?.FlightId != prevInboundFlightId
            || OutboundFlight?.FlightId != prevOutboundFlightId;

        prevInboundFlightId = InboundFlight?.FlightId ?? 0;
        prevOutboundFlightId = OutboundFlight?.FlightId ?? 0;
    }

    protected override bool ShouldRender() => shouldRender;
}
```

An event handler can also set `shouldRender` to `true`. For most components, determining rerendering at the level of individual event handlers usually isn't necessary.

For more information, see the following resources:

- ASP.NET Core Razor component lifecycle
- ShouldRender
- ASP.NET Core Razor component rendering

Virtualization

When rendering large amounts of UI within a loop, for example, a list or grid with thousands of entries, the sheer quantity of rendering operations can lead to a lag in UI rendering. Given that the user can only see a small number of elements at once without scrolling, it's often wasteful to spend time rendering elements that aren't currently visible.

Blazor provides the Virtualize<TItem> component to create the appearance and scroll behaviors of an arbitrarily-large list while only rendering the list items that are within the current scroll viewport. For example, a component can render a list with 100,000 entries but only pay the rendering cost of 20 items that are visible.

For more information, see ASP.NET Core Razor component virtualization.

Create lightweight, optimized components

Most Razor components don't require aggressive optimization efforts because most components don't repeat in the UI and don't rerender at high frequency. For example,

routable components with an `@page` directive and components used to render high-level pieces of the UI, such as dialogs or forms, most likely appear only one at a time and only rerender in response to a user gesture. These components don't usually create high rendering workload, so you can freely use any combination of framework features without much concern about rendering performance.

However, there are common scenarios where components are repeated at scale and often result in poor UI performance:

- Large nested forms with hundreds of individual elements, such as inputs or labels.
- Grids with hundreds of rows or thousands of cells.
- Scatter plots with millions of data points.

If modelling each element, cell, or data point as a separate component instance, there are often so many of them that their rendering performance becomes critical. This section provides advice on making such components lightweight so that the UI remains fast and responsive.

Avoid thousands of component instances

Each component is a separate island that can render independently of its parents and children. By choosing how to split the UI into a hierarchy of components, you are taking control over the granularity of UI rendering. This can result in either good or poor performance.

By splitting the UI into separate components, you can have smaller portions of the UI rerender when events occur. In a table with many rows that have a button in each row, you may be able to have only that single row rerender by using a child component instead of the whole page or table. However, each component requires additional memory and CPU overhead to deal with its independent state and rendering lifecycle.

In a test performed by the ASP.NET Core product unit engineers, a rendering overhead of around 0.06 ms per component instance was seen in a Blazor WebAssembly app. The test app rendered a simple component that accepts three parameters. Internally, the overhead is largely due to retrieving per-component state from dictionaries and passing and receiving parameters. By multiplication, you can see that adding 2,000 extra component instances would add 0.12 seconds to the rendering time and the UI would begin feeling slow to users.

It's possible to make components more lightweight so that you can have more of them. However, a more powerful technique is often to avoid having so many components to render. The following sections describe two approaches that you can take.

For more information on memory management, see Host and deploy ASP.NET Core server-side Blazor apps.

Inline child components into their parents

Consider the following portion of a parent component that renders child components in a loop:

razor

```razor
<div class="chat">
    @foreach (var message in messages)
    {
        <ChatMessageDisplay Message="message" />
    }
</div>
```

`ChatMessageDisplay.razor`:

razor

```razor
<div class="chat-message">
    <span class="author">@Message.Author</span>
    <span class="text">@Message.Text</span>
</div>

@code {
    [Parameter]
    public ChatMessage? Message { get; set; }
}
```

The preceding example performs well if thousands of messages aren't shown at once. To show thousands of messages at once, consider *not* factoring out the separate `ChatMessageDisplay` component. Instead, inline the child component into the parent. The following approach avoids the per-component overhead of rendering so many child components at the cost of losing the ability to rerender each child component's markup independently:

razor

```razor
<div class="chat">
    @foreach (var message in messages)
    {
        <div class="chat-message">
            <span class="author">@message.Author</span>
            <span class="text">@message.Text</span>
        </div>
```

```
    }
</div>
```

Define reusable `RenderFragments` in code

You might be factoring out child components purely as a way of reusing rendering logic. If that's the case, you can create reusable rendering logic without implementing additional components. In any component's `@code` block, define a RenderFragment. Render the fragment from any location as many times as needed:

razor

```
@RenderWelcomeInfo

<p>Render the welcome content a second time:</p>

@RenderWelcomeInfo

@code {
    private RenderFragment RenderWelcomeInfo = @<p>Welcome to your new app!
</p>;
}
```

To make RenderTreeBuilder code reusable across multiple components, declare the RenderFragment public and static:

razor

```
public static RenderFragment SayHello = @<h1>Hello!</h1>;
```

`SayHello` in the preceding example can be invoked from an unrelated component. This technique is useful for building libraries of reusable markup snippets that render without per-component overhead.

RenderFragment delegates can accept parameters. The following component passes the message (`message`) to the RenderFragment delegate:

razor

```
<div class="chat">
    @foreach (var message in messages)
    {
        @ChatMessageDisplay(message)
    }
</div>
```

```
@code {
    private RenderFragment<ChatMessage> ChatMessageDisplay = message =>
        @<div class="chat-message">
            <span class="author">@message.Author</span>
            <span class="text">@message.Text</span>
        </div>;
}
```

The preceding approach reuses rendering logic without per-component overhead. However, the approach doesn't permit refreshing the subtree of the UI independently, nor does it have the ability to skip rendering the subtree of the UI when its parent renders because there's no component boundary. Assignment to a RenderFragment delegate is only supported in Razor component files (`.razor`), and event callbacks aren't supported.

For a non-static field, method, or property that can't be referenced by a field initializer, such as `TitleTemplate` in the following example, use a property instead of a field for the RenderFragment:

C#

```
protected RenderFragment DisplayTitle =>
    @<div>
        @TitleTemplate
    </div>;
```

Don't receive too many parameters

If a component repeats extremely often, for example, hundreds or thousands of times, the overhead of passing and receiving each parameter builds up.

It's rare that too many parameters severely restricts performance, but it can be a factor. For a `TableCell` component that renders 4,000 times within a grid, each parameter passed to the component adds around 15 ms to the total rendering cost. Passing ten parameters requires around 150 ms and causes a UI rendering lag.

To reduce parameter load, bundle multiple parameters in a custom class. For example, a table cell component might accept a common object. In the following example, `Data` is different for every cell, but `Options` is common across all cell instances:

razor

```
@typeparam TItem

...
```

```
@code {
    [Parameter]
    public TItem? Data { get; set; }

    [Parameter]
    public GridOptions? Options { get; set; }
}
```

However, consider that it might be an improvement not to have a table cell component, as shown in the preceding example, and instead inline its logic into the parent component.

> **Note**
>
> When multiple approaches are available for improving performance, benchmarking the approaches is usually required to determine which approach yields the best results.

For more information on generic type parameters (`@typeparam`), see the following resources:

- Razor syntax reference for ASP.NET Core
- ASP.NET Core Razor components
- ASP.NET Core Blazor templated components

Ensure cascading parameters are fixed

The CascadingValue component has an optional `IsFixed` parameter:

- If `IsFixed` is `false` (the default), every recipient of the cascaded value sets up a subscription to receive change notifications. Each `[CascadingParameter]` is **substantially more expensive** than a regular `[Parameter]` due to the subscription tracking.
- If `IsFixed` is `true` (for example, `<CascadingValue Value="someValue" IsFixed="true">`), recipients receive the initial value but don't set up a subscription to receive updates. Each `[CascadingParameter]` is lightweight and no more expensive than a regular `[Parameter]`.

Setting `IsFixed` to `true` improves performance if there are a large number of other components that receive the cascaded value. Wherever possible, set `IsFixed` to `true` on

cascaded values. You can set `IsFixed` to `true` when the supplied value doesn't change over time.

Where a component passes `this` as a cascaded value, `IsFixed` can also be set to `true`:

```razor
<CascadingValue Value="this" IsFixed="true">
    <SomeOtherComponents>
</CascadingValue>
```

For more information, see ASP.NET Core Blazor cascading values and parameters.

Avoid attribute splatting with `CaptureUnmatchedValues`

Components can elect to receive "unmatched" parameter values using the CaptureUnmatchedValues flag:

```razor
<div @attributes="OtherAttributes">...</div>

@code {
    [Parameter(CaptureUnmatchedValues = true)]
    public IDictionary<string, object>? OtherAttributes { get; set; }
}
```

This approach allows passing arbitrary additional attributes to the element. However, this approach is expensive because the renderer must:

- Match all of the supplied parameters against the set of known parameters to build a dictionary.
- Keep track of how multiple copies of the same attribute overwrite each other.

Use CaptureUnmatchedValues where component rendering performance isn't critical, such as components that aren't repeated frequently. For components that render at scale, such as each item in a large list or in the cells of a grid, try to avoid attribute splatting.

For more information, see ASP.NET Core Blazor attribute splatting and arbitrary parameters.

Implement `SetParametersAsync` manually

A significant source of per-component rendering overhead is writing incoming parameter values to `[Parameter]` properties. The renderer uses reflection to write the parameter values, which can lead to poor performance at scale.

In some extreme cases, you may wish to avoid the reflection and implement your own parameter-setting logic manually. This may be applicable when:

- A component renders extremely often, for example, when there are hundreds or thousands of copies of the component in the UI.
- A component accepts many parameters.
- You find that the overhead of receiving parameters has an observable impact on UI responsiveness.

In extreme cases, you can override the component's virtual SetParametersAsync method and implement your own component-specific logic. The following example deliberately avoids dictionary lookups:

razor

```
@code {
    [Parameter]
    public int MessageId { get; set; }

    [Parameter]
    public string? Text { get; set; }

    [Parameter]
    public EventCallback<string> TextChanged { get; set; }

    [Parameter]
    public Theme CurrentTheme { get; set; }

    public override Task SetParametersAsync(ParameterView parameters)
    {
        foreach (var parameter in parameters)
        {
            switch (parameter.Name)
            {
                case nameof(MessageId):
                    MessageId = (int)parameter.Value;
                    break;
                case nameof(Text):
                    Text = (string)parameter.Value;
                    break;
                case nameof(TextChanged):
                    TextChanged = (EventCallback<string>)parameter.Value;
                    break;
                case nameof(CurrentTheme):
                    CurrentTheme = (Theme)parameter.Value;
                    break;
```

```
                default:
                    throw new ArgumentException($"Unknown parameter:
{parameter.Name}");
            }
        }

        return base.SetParametersAsync(ParameterView.Empty);
    }
}
```

In the preceding code, returning the base class SetParametersAsync runs the normal lifecycle method without assigning parameters again.

As you can see in the preceding code, overriding SetParametersAsync and supplying custom logic is complicated and laborious, so we don't generally recommend adopting this approach. In extreme cases, it can improve rendering performance by 20-25%, but you should only consider this approach in the extreme scenarios listed earlier in this section.

Don't trigger events too rapidly

Some browser events fire extremely frequently. For example, `onmousemove` and `onscroll` can fire tens or hundreds of times per second. In most cases, you don't need to perform UI updates this frequently. If events are triggered too rapidly, you may harm UI responsiveness or consume excessive CPU time.

Rather than use native events that rapidly fire, consider the use of JS interop to register a callback that fires less frequently. For example, the following component displays the position of the mouse but only updates at most once every 500 ms:

razor

```
@implements IDisposable
@inject IJSRuntime JS

<h1>@message</h1>

<div @ref="mouseMoveElement" style="border:1px dashed red;height:200px;">
    Move mouse here
</div>

@code {
    private ElementReference mouseMoveElement;
    private DotNetObjectReference<MyComponent>? selfReference;
    private string message = "Move the mouse in the box";

    [JSInvokable]
    public void HandleMouseMove(int x, int y)
```

```
    {
        message = $"Mouse move at {x}, {y}";
        StateHasChanged();
    }

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            selfReference = DotNetObjectReference.Create(this);
            var minInterval = 500;

            await JS.InvokeVoidAsync("onThrottledMouseMove",
                mouseMoveElement, selfReference, minInterval);
        }
    }

    public void Dispose() => selfReference?.Dispose();
}
```

The corresponding JavaScript code registers the DOM event listener for mouse movement. In this example, the event listener uses Lodash's throttle function to limit the rate of invocations:

HTML

```
<script
src="https://cdnjs.cloudflare.com/ajax/libs/lodash.js/4.17.20/lodash.min.js"
></script>
<script>
  function onThrottledMouseMove(elem, component, interval) {
    elem.addEventListener('mousemove', _.throttle(e => {
      component.invokeMethodAsync('HandleMouseMove', e.offsetX, e.offsetY);
    }, interval));
  }
</script>
```

Avoid rerendering after handling events without state changes

Components inherit from ComponentBase, which automatically invokes StateHasChanged after the component's event handlers are invoked. In some cases, it might be unnecessary or undesirable to trigger a rerender after an event handler is invoked. For example, an event handler might not modify component state. In these scenarios, the app can leverage the IHandleEvent interface to control the behavior of Blazor's event handling.

> **Note**
>
> The approach in this section doesn't flow exceptions to error boundaries. For more information and demonstration code that supports error boundaries by calling ComponentBase.DispatchExceptionAsync, see AsNonRenderingEventHandler + ErrorBoundary = unexpected behavior (dotnet/aspnetcore #54543).

To prevent rerenders for all of a component's event handlers, implement IHandleEvent and provide a IHandleEvent.HandleEventAsync task that invokes the event handler without calling StateHasChanged.

In the following example, no event handler added to the component triggers a rerender, so `HandleSelect` doesn't result in a rerender when invoked.

`HandleSelect1.razor`:

razor

```
@page "/handle-select-1"
@using Microsoft.Extensions.Logging
@implements IHandleEvent
@inject ILogger<HandleSelect1> Logger

<p>
    Last render DateTime: @dt
</p>

<button @onclick="HandleSelect">
    Select me (Avoids Rerender)
</button>

@code {
    private DateTime dt = DateTime.Now;

    private void HandleSelect()
    {
        dt = DateTime.Now;

        Logger.LogInformation("This event handler doesn't trigger a
rerender.");
    }

    Task IHandleEvent.HandleEventAsync(
        EventCallbackWorkItem callback, object? arg) =>
callback.InvokeAsync(arg);
}
```

In addition to preventing rerenders after event handlers fire in a component in a global fashion, it's possible to prevent rerenders after a single event handler by employing the following utility method.

Add the following `EventUtil` class to a Blazor app. The static actions and functions at the top of the `EventUtil` class provide handlers that cover several combinations of arguments and return types that Blazor uses when handling events.

`EventUtil.cs`:

C#

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Components;

public static class EventUtil
{
    public static Action AsNonRenderingEventHandler(Action callback)
        => new SyncReceiver(callback).Invoke;
    public static Action<TValue> AsNonRenderingEventHandler<TValue>(
            Action<TValue> callback)
        => new SyncReceiver<TValue>(callback).Invoke;
    public static Func<Task> AsNonRenderingEventHandler(Func<Task> callback)
        => new AsyncReceiver(callback).Invoke;
    public static Func<TValue, Task> AsNonRenderingEventHandler<TValue>(
            Func<TValue, Task> callback)
        => new AsyncReceiver<TValue>(callback).Invoke;

    private record SyncReceiver(Action callback)
        : ReceiverBase { public void Invoke() => callback(); }
    private record SyncReceiver<T>(Action<T> callback)
        : ReceiverBase { public void Invoke(T arg) => callback(arg); }
    private record AsyncReceiver(Func<Task> callback)
        : ReceiverBase { public Task Invoke() => callback(); }
    private record AsyncReceiver<T>(Func<T, Task> callback)
        : ReceiverBase { public Task Invoke(T arg) => callback(arg); }

    private record ReceiverBase : IHandleEvent
    {
        public Task HandleEventAsync(EventCallbackWorkItem item, object arg)
=>
            item.InvokeAsync(arg);
    }
}
```

Call `EventUtil.AsNonRenderingEventHandler` to call an event handler that doesn't trigger a render when invoked.

In the following example:

- Selecting the first button, which calls `HandleClick1`, triggers a rerender.
- Selecting the second button, which calls `HandleClick2`, doesn't trigger a rerender.
- Selecting the third button, which calls `HandleClick3`, doesn't trigger a rerender and uses event arguments (MouseEventArgs).

`HandleSelect2.razor`:

razor

```
@page "/handle-select-2"
@using Microsoft.Extensions.Logging
@inject ILogger<HandleSelect2> Logger

<p>
    Last render DateTime: @dt
</p>

<button @onclick="HandleClick1">
    Select me (Rerenders)
</button>

<button @onclick="EventUtil.AsNonRenderingEventHandler(HandleClick2)">
    Select me (Avoids Rerender)
</button>

<button @onclick="EventUtil.AsNonRenderingEventHandler<MouseEventArgs>
(HandleClick3)">
    Select me (Avoids Rerender and uses <code>MouseEventArgs</code>)
</button>

@code {
    private DateTime dt = DateTime.Now;

    private void HandleClick1()
    {
        dt = DateTime.Now;

        Logger.LogInformation("This event handler triggers a rerender.");
    }

    private void HandleClick2()
    {
        dt = DateTime.Now;

        Logger.LogInformation("This event handler doesn't trigger a
rerender.");
    }

    private void HandleClick3(MouseEventArgs args)
    {
        dt = DateTime.Now;
```

```
        Logger.LogInformation(
            "This event handler doesn't trigger a rerender. " +
            "Mouse coordinates: {ScreenX}:{ScreenY}",
            args.ScreenX, args.ScreenY);
    }
}
```

In addition to implementing the IHandleEvent interface, leveraging the other best practices described in this article can also help reduce unwanted renders after events are handled. For example, overriding ShouldRender in child components of the target component can be used to control rerendering.

Avoid recreating delegates for many repeated elements or components

Blazor's recreation of lambda expression delegates for elements or components in a loop can lead to poor performance.

The following component shown in the event handling article renders a set of buttons. Each button assigns a delegate to its `@onclick` event, which is fine if there aren't many buttons to render.

`EventHandlerExample5.razor`:

razor

```
@page "/event-handler-example-5"

<h1>@heading</h1>

@for (var i = 1; i < 4; i++)
{
    var buttonNumber = i;

    <p>
        <button @onclick="@(e => UpdateHeading(e, buttonNumber))">
            Button #@i
        </button>
    </p>
}

@code {
    private string heading = "Select a button to learn its position";

    private void UpdateHeading(MouseEventArgs e, int buttonNumber)
    {
        heading = $"Selected #{buttonNumber} at {e.ClientX}:{e.ClientY}";
```

```
    }
}
```

If a large number of buttons are rendered using the preceding approach, rendering speed is adversely impacted leading to a poor user experience. To render a large number of buttons with a callback for click events, the following example uses a collection of button objects that assign each button's `@onclick` delegate to an Action. The following approach doesn't require Blazor to rebuild all of the button delegates each time the buttons are rendered:

`LambdaEventPerformance.razor`:

razor

```
@page "/lambda-event-performance"

<h1>@heading</h1>

@foreach (var button in Buttons)
{
    <p>
        <button @key="button.Id" @onclick="button.Action">
            Button #@button.Id
        </button>
    </p>
}

@code {
    private string heading = "Select a button to learn its position";

    private List<Button> Buttons { get; set; } = new();

    protected override void OnInitialized()
    {
        for (var i = 0; i < 100; i++)
        {
            var button = new Button();

            button.Id = Guid.NewGuid().ToString();

            button.Action = (e) =>
            {
                UpdateHeading(button, e);
            };

            Buttons.Add(button);
        }
    }

    private void UpdateHeading(Button button, MouseEventArgs e)
    {
```

```
        heading = $"Selected #{button.Id} at {e.ClientX}:{e.ClientY}";
    }

    private class Button
    {
        public string? Id { get; set; }
        public Action<MouseEventArgs> Action { get; set; } = e => { };
    }
}
```

Optimize JavaScript interop speed

Calls between .NET and JavaScript require additional overhead because:

- Calls are asynchronous.
- Parameters and return values are JSON-serialized to provide an easy-to-understand conversion mechanism between .NET and JavaScript types.

Additionally for server-side Blazor apps, these calls are passed across the network.

Avoid excessively fine-grained calls

Since each call involves some overhead, it can be valuable to reduce the number of calls. Consider the following code, which stores a collection of items in the browser's localStorage:

C#

```
private async Task StoreAllInLocalStorage(IEnumerable<TodoItem> items)
{
    foreach (var item in items)
    {
        await JS.InvokeVoidAsync("localStorage.setItem", item.Id,
            JsonSerializer.Serialize(item));
    }
}
```

The preceding example makes a separate JS interop call for each item. Instead, the following approach reduces the JS interop to a single call:

C#

```
private async Task StoreAllInLocalStorage(IEnumerable<TodoItem> items)
{
```

```
    await JS.InvokeVoidAsync("storeAllInLocalStorage", items);
}
```

The corresponding JavaScript function stores the whole collection of items on the client:

JavaScript

```
function storeAllInLocalStorage(items) {
  items.forEach(item => {
    localStorage.setItem(item.id, JSON.stringify(item));
  });
}
```

For Blazor WebAssembly apps, rolling individual JS interop calls into a single call usually only improves performance significantly if the component makes a large number of JS interop calls.

Consider the use of synchronous calls

Call JavaScript from .NET

This section only applies to client-side components.

JS interop calls are asynchronous, regardless of whether the called code is synchronous or asynchronous. Calls are asynchronous to ensure that components are compatible across server-side and client-side render modes. On the server, all JS interop calls must be asynchronous because they're sent over a network connection.

If you know for certain that your component only runs on WebAssembly, you can choose to make synchronous JS interop calls. This has slightly less overhead than making asynchronous calls and can result in fewer render cycles because there's no intermediate state while awaiting results.

To make a synchronous call from .NET to JavaScript in a client-side component, cast IJSRuntime to IJSInProcessRuntime to make the JS interop call:

razor

```
@inject IJSRuntime JS

...

@code {
    protected override void HandleSomeEvent()
    {
```

```
        var jsInProcess = (IJSInProcessRuntime)JS;
        var value = jsInProcess.Invoke<string>
("javascriptFunctionIdentifier");
    }
}
```

When working with IJSObjectReference in ASP.NET Core 5.0 or later client-side components, you can use IJSInProcessObjectReference synchronously instead. IJSInProcessObjectReference implements IAsyncDisposable/IDisposable and should be disposed for garbage collection to prevent a memory leak, as the following example demonstrates:

razor

```
@inject IJSRuntime JS
@implements IAsyncDisposable

...

@code {
    ...
    private IJSInProcessObjectReference? module;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            module = await JS.InvokeAsync<IJSInProcessObjectReference>
("import",
            "./scripts.js");
        }
    }

    ...

    async ValueTask IAsyncDisposable.DisposeAsync()
    {
        if (module is not null)
        {
            await module.DisposeAsync();
        }
    }
}
```

Call .NET from JavaScript

This section only applies to client-side components.

JS interop calls are asynchronous, regardless of whether the called code is synchronous or asynchronous. Calls are asynchronous to ensure that components are compatible across server-side and client-side render modes. On the server, all JS interop calls must be asynchronous because they're sent over a network connection.

If you know for certain that your component only runs on WebAssembly, you can choose to make synchronous JS interop calls. This has slightly less overhead than making asynchronous calls and can result in fewer render cycles because there's no intermediate state while awaiting results.

To make a synchronous call from JavaScript to .NET in a client-side component, use `DotNet.invokeMethod` instead of `DotNet.invokeMethodAsync`.

Synchronous calls work if:

- The component is only rendered for execution on WebAssembly.
- The called function returns a value synchronously. The function isn't an `async` method and doesn't return a .NET Task or JavaScript Promise.

Use JavaScript `[JSImport]`/`[JSExport]` interop

JavaScript `[JSImport]`/`[JSExport]` interop for Blazor WebAssembly apps offers improved performance and stability over the JS interop API in framework releases prior to ASP.NET Core in .NET 7.

For more information, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

Ahead-of-time (AOT) compilation

Ahead-of-time (AOT) compilation compiles a Blazor app's .NET code directly into native WebAssembly for direct execution by the browser. AOT-compiled apps result in larger apps that take longer to download, but AOT-compiled apps usually provide better runtime performance, especially for apps that execute CPU-intensive tasks. For more information, see ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation.

Minimize app download size

Runtime relinking

For information on how runtime relinking minimizes an app's download size, see ASP.NET Core Blazor WebAssembly build tools and ahead-of-time (AOT) compilation.

Use `System.Text.Json`

Blazor's JS interop implementation relies on System.Text.Json, which is a high-performance JSON serialization library with low memory allocation. Using System.Text.Json shouldn't result in additional app payload size over adding one or more alternate JSON libraries.

For migration guidance, see How to migrate from Newtonsoft.Json to System.Text.Json.

Intermediate Language (IL) trimming

This section only applies to client-side Blazor scenarios.

Trimming unused assemblies from a Blazor WebAssembly app reduces the app's size by removing unused code in the app's binaries. For more information, see Configure the Trimmer for ASP.NET Core Blazor.

Lazy load assemblies

This section only applies to client-side Blazor scenarios.

Load assemblies at runtime when the assemblies are required by a route. For more information, see Lazy load assemblies in ASP.NET Core Blazor WebAssembly.

Compression

This section only applies to Blazor WebAssembly apps.

When a Blazor WebAssembly app is published, the output is statically compressed during publish to reduce the app's size and remove the overhead for runtime compression. Blazor relies on the server to perform content negotiation and serve statically-compressed files.

After an app is deployed, verify that the app serves compressed files. Inspect the **Network** tab in a browser's developer tools and verify that the files are served with `Content-Encoding: br` (Brotli compression) or `Content-Encoding: gz` (Gzip compression). If the host isn't serving compressed files, follow the instructions in Host and deploy ASP.NET Core Blazor WebAssembly.

Disable unused features

This section only applies to client-side Blazor scenarios.

Blazor WebAssembly's runtime includes the following .NET features that can be disabled for a smaller payload size:

- Blazor WebAssembly carries globalization resources required to display values, such as dates and currency, in the user's culture. If the app doesn't require localization, you may configure the app to support the invariant culture, which is based on the `en-US` culture.

- Adopting invariant globalization only results in using non-localized timezone names. To trim timezone code and data from the app, apply the `<InvariantTimezone>` MSBuild property with a value of `true` in the app's project file:

  XML

  ```
  <PropertyGroup>
    <InvariantTimezone>true</InvariantTimezone>
  </PropertyGroup>
  ```

  > **Note**
  >
  > `<BlazorEnableTimeZoneSupport>` overrides an earlier `<InvariantTimezone>` setting. We recommend removing the `<BlazorEnableTimeZoneSupport>` setting.

Test Razor components in ASP.NET Core Blazor

Article • 03/08/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Egil Hansen

Testing Razor components is an important aspect of releasing stable and maintainable Blazor apps.

To test a Razor component, the *component under test* (CUT) is:

- Rendered with relevant input for the test.
- Depending on the type of test performed, possibly subject to interaction or modification. For example, event handlers can be triggered, such as an `onclick` event for a button.
- Inspected for expected values. A test passes when one or more inspected values matches the expected values for the test.

Test approaches

Two common approaches for testing Razor components are end-to-end (E2E) testing and unit testing:

- **Unit testing**: Unit tests are written with a unit testing library that provides:
  - Component rendering.
  - Inspection of component output and state.
  - Triggering of event handlers and life cycle methods.
  - Assertions that component behavior is correct.

  bUnit is an example of a library that enables Razor component unit testing.

- **E2E testing**: A test runner runs a Blazor app containing the CUT and automates a browser instance. The testing tool inspects and interacts with the CUT through the browser. Playwright for .NET is an example of an E2E testing framework that can be used with Blazor apps.

In unit testing, only the Razor component (Razor/C#) is involved. External dependencies, such as services and JS interop, must be mocked. In E2E testing, the Razor component and all of its auxiliary infrastructure are part of the test, including CSS, JS, and the DOM and browser APIs.

Test scope describes how extensive the tests are. Test scope typically has an influence on the speed of the tests. Unit tests run on a subset of the app's subsystems and usually execute in milliseconds. E2E tests, which test a broad group of the app's subsystems, can take several seconds to complete.

Unit testing also provides access to the instance of the CUT, allowing for inspection and verification of the component's internal state. This normally isn't possible in E2E testing.

With regard to the component's environment, E2E tests must make sure that the expected environmental state has been reached before verification starts. Otherwise, the result is unpredictable. In unit testing, the rendering of the CUT and the life cycle of the test are more integrated, which improves test stability.

E2E testing involves launching multiple processes, network and disk I/O, and other subsystem activity that often lead to poor test reliability. Unit tests are typically insulated from these sorts of issues.

The following table summarizes the difference between the two testing approaches.

Expand table

Capability	Unit testing	E2E testing
Test scope	Razor component (Razor/C#) only	Razor component (Razor/C#) with CSS/JS
Test execution time	Milliseconds	Seconds
Access to the component instance	Yes	No
Sensitive to the environment	No	Yes
Reliability	More reliable	Less reliable

Choose the most appropriate test approach

Consider the scenario when choosing the type of testing to perform. Some considerations are described in the following table.

Expand table

Scenario	Suggested approach	Remarks
Component without JS interop logic	Unit testing	When there's no dependency on JS interop in a Razor component, the component can be tested without access to JS or the DOM API. In this scenario, there are no disadvantages to choosing unit testing.
Component with simple JS interop logic	Unit testing	It's common for components to query the DOM or trigger animations through JS interop. Unit testing is usually preferred in this scenario, since it's straightforward to mock the JS interaction through the IJSRuntime interface.
Component that depends on complex JS code	Unit testing and separate JS testing	If a component uses JS interop to call a large or complex JS library but the interaction between the Razor component and JS library is simple, then the best approach is likely to treat the component and JS library or code as two separate parts and test each individually. Test the Razor component with a unit testing library, and test the JS with a JS testing library.
Component with logic that depends on JS manipulation of the browser DOM	E2E testing	When a component's functionality is dependent on JS and its manipulation of the DOM, verify both the JS and Blazor code together in an E2E test. This is the approach that the Blazor framework developers have taken with Blazor's browser rendering logic, which has tightly-coupled C# and JS code. The C# and JS code must work together to correctly render Razor components in a browser.
Component that depends on 3rd party class library with hard-to-mock dependencies	E2E testing	When a component's functionality is dependent on a 3rd party class library that has hard-to-mock dependencies, such as JS interop, E2E testing might be the only option to test the component.

Test components with bUnit

There's no official Microsoft testing framework for Blazor, but the community-driven project bUnit provides a convenient way to unit test Razor components.

> **Note**
>
> bUnit is a third-party testing library and isn't supported or maintained by Microsoft.

bUnit works with general-purpose testing frameworks, such as MSTest, NUnit, and xUnit. These testing frameworks make bUnit tests look and feel like regular unit tests. bUnit tests integrated with a general-purpose testing framework are ordinarily executed with:

- Visual Studio's Test Explorer.
- dotnet test CLI command in a command shell.
- An automated DevOps testing pipeline.

> **Note**
>
> Test concepts and test implementations across different test frameworks are similar but not identical. Refer to the test framework's documentation for guidance.

The following demonstrates the structure of a bUnit test on the `Counter` component in an app based on a Blazor project template. The `Counter` component displays and increments a counter based on the user selecting a button in the page:

razor

```razor
@page "/counter"

<h1>Counter</h1>

<p>Current count: @currentCount</p>

<button class="btn btn-primary" @onclick="IncrementCount">Click me</button>

@code {
    private int currentCount = 0;

    private void IncrementCount()
    {
        currentCount++;
    }
}
```

The following bUnit test verifies that the CUT's counter is incremented correctly when the button is selected:

razor

```
@code {
    [Fact]
    public void CounterShouldIncrementWhenClicked()
    {
        // Arrange
        using var ctx = new TestContext();
        var cut = ctx.Render(@<Counter />);
        var paraElm = cut.Find("p");

        // Act
        cut.Find("button").Click();

        // Assert
        var paraElmText = paraElm.TextContent;
        paraElm.MarkupMatches("Current count: 1");
    }
}
```

Tests can also be written in a C# class file:

C#

```
public class CounterTests
{
    [Fact]
    public void CounterShouldIncrementWhenClicked()
    {
        // Arrange
        using var ctx = new TestContext();
        var cut = ctx.RenderComponent<Counter>();
        var paraElm = cut.Find("p");

        // Act
        cut.Find("button").Click();

        // Assert
        var paraElmText = paraElm.TextContent;
        paraElmText.MarkupMatches("Current count: 1");
    }
}
```

The following actions take place at each step of the test:

- *Arrange*: The `Counter` component is rendered using bUnit's `TestContext`. The CUT's paragraph element (`<p>`) is found and assigned to `paraElm`. In Razor syntax,

a component can be passed as a RenderFragment to bUnit.

- *Act*: The button's element (`<button>`) is located and selected by calling `Click`, which should increment the counter and update the content of the paragraph tag (`<p>`). The paragraph element text content is obtained by calling `TextContent`.
- *Assert*: `MarkupMatches` is called on the text content to verify that it matches the expected string, which is `Current count: 1`.

> **Note**
>
> The `MarkupMatches` assert method differs from a regular string comparison assertion (for example, `Assert.Equal("Current count: 1", paraElmText);`). `MarkupMatches` performs a semantic comparison of the input and expected HTML markup. A semantic comparison is aware of HTML semantics, meaning things like insignificant whitespace is ignored. This results in more stable tests. For more information, see Customizing the Semantic HTML Comparison.

ASP.NET Core Blazor Progressive Web Application (PWA)

Article • 11/06/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

A Blazor Progressive Web Application (PWA) is a single-page application (SPA) that uses modern browser APIs and capabilities to behave like a desktop app.

Blazor WebAssembly is a standards-based client-side web app platform, so it can use any browser API, including PWA APIs required for the following capabilities:

- Working offline and loading instantly, independent of network speed.
- Running in its own app window, not just a browser window.
- Being launched from the host's operating system start menu, dock, or home screen.
- Receiving push notifications from a backend server, even while the user isn't using the app.
- Automatically updating in the background.

The word *progressive* is used to describe these apps because:

- A user might first discover and use the app within their web browser like any other SPA.
- Later, the user progresses to installing it in their OS and enabling push notifications.

Create a project from the PWA template

Visual Studio

When creating a new **Blazor WebAssembly App**, select the **Progressive Web Application** checkbox.

Convert an existing Blazor WebAssembly app into a PWA

Convert an existing Blazor WebAssembly app into a PWA following the guidance in this section.

In the app's project file:

- Add the following `ServiceWorkerAssetsManifest` property to a `PropertyGroup`:

  XML

  ```
    ...
    <ServiceWorkerAssetsManifest>service-worker-
  assets.js</ServiceWorkerAssetsManifest>
  </PropertyGroup>
  ```

- Add the following `ServiceWorker` item to an `ItemGroup`:

  XML

  ```
  <ItemGroup>
    <ServiceWorker Include="wwwroot\service-worker.js"
      PublishedContent="wwwroot\service-worker.published.js" />
  </ItemGroup>
  ```

To obtain static assets, use **one** of the following approaches:

- Create a separate, new PWA project with the dotnet new command in a command shell:

  .NET CLI

  ```
  dotnet new blazorwasm -o MyBlazorPwa --pwa
  ```

  In the preceding command, the `-o|--output` option creates a new folder for the app named `MyBlazorPwa`.

  If you aren't converting an app for the latest release, pass the `-f|--framework` option. The following example creates the app for ASP.NET Core version 5.0:

  .NET CLI

  ```
  dotnet new blazorwasm -o MyBlazorPwa --pwa -f net5.0
  ```

- Navigate to the ASP.NET Core GitHub repository at the following URL, which links to `main` branch reference source and assets. Select the release that you're working with from the **Switch branches or tags** dropdown list that applies to your app.

  Blazor WebAssembly project template wwwroot folder (dotnet/aspnetcore GitHub repository main branch)

  > **Note**
  >
  > Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

  From the source `wwwroot` folder either in the app that you created or from the reference assets in the `dotnet/aspnetcore` GitHub repository, copy the following files into the app's `wwwroot` folder:

  - `icon-192.png`
  - `icon-512.png`
  - `manifest.webmanifest`
  - `service-worker.js`
  - `service-worker.published.js`

In the app's `wwwroot/index.html` file:

- Add `<link>` elements for the manifest and app icon:

  HTML

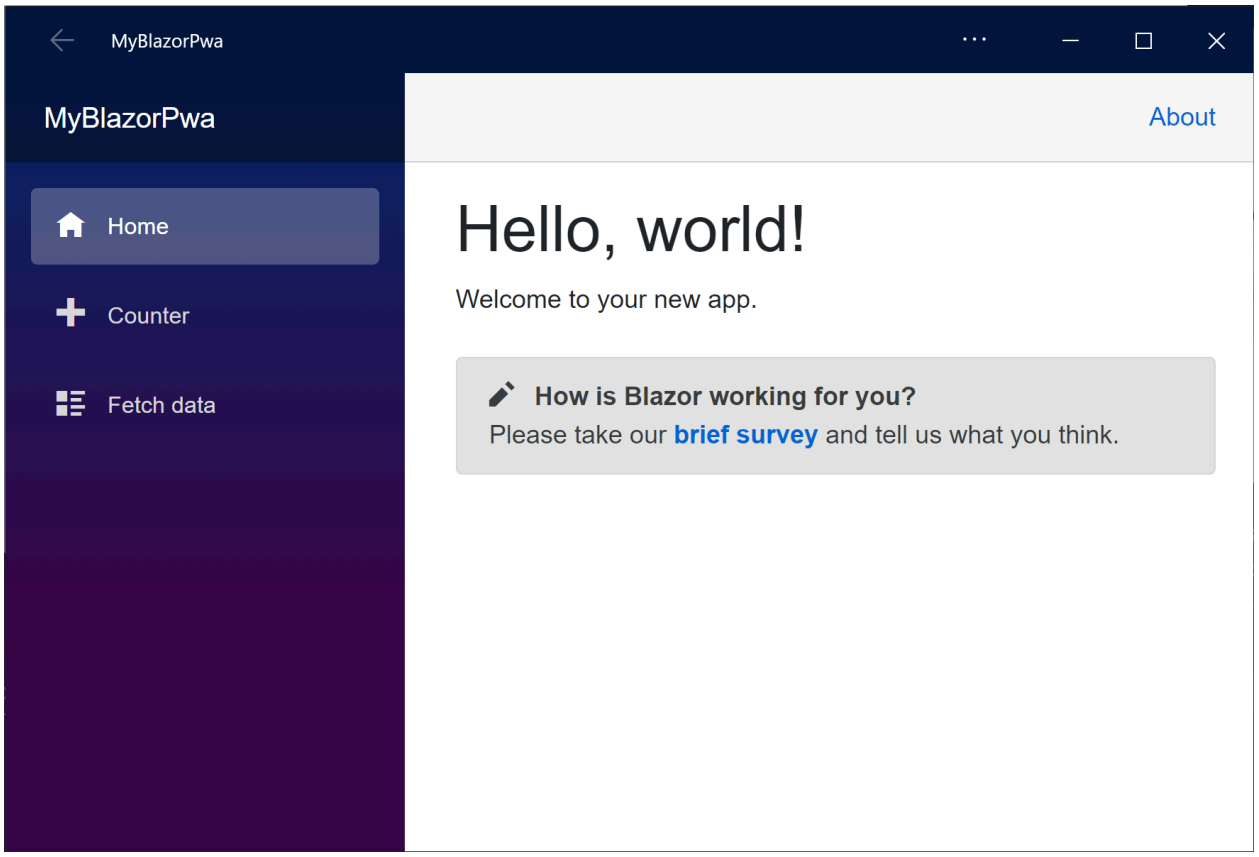
  ```
  <link href="manifest.webmanifest" rel="manifest" />
  <link rel="apple-touch-icon" sizes="512x512" href="icon-512.png" />
  <link rel="apple-touch-icon" sizes="192x192" href="icon-192.png" />
  ```

- Add the following `<script>` tag inside the closing `</body>` tag immediately after the `blazor.webassembly.js` script tag:

  HTML

  ```
      ...
      <script>navigator.serviceWorker.register('service-worker.js');
  ```

```
</script>
</body>
```



Installation and app manifest

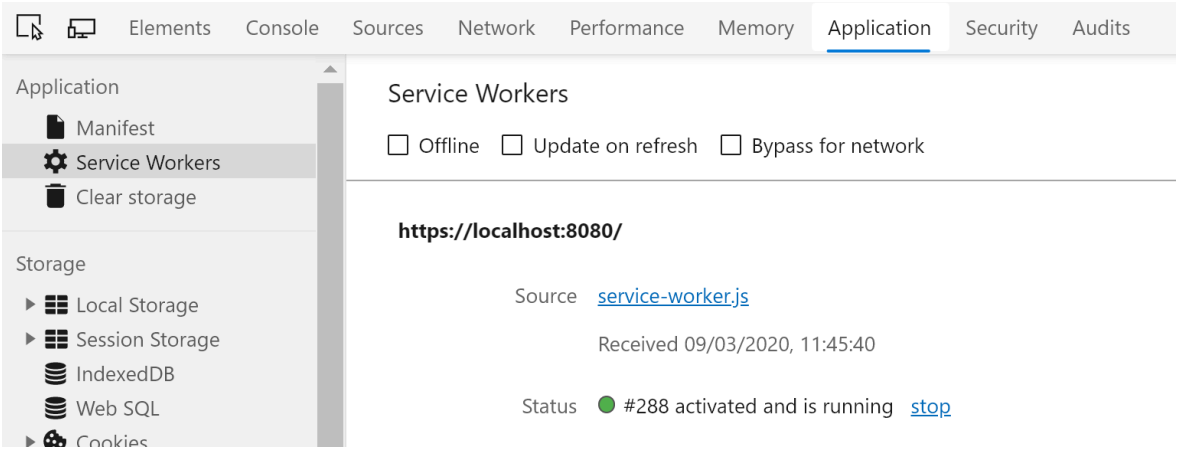
When visiting an app created using the PWA template, users have the option of installing the app into their OS's start menu, dock, or home screen. The way this option is presented depends on the user's browser. When using desktop Chromium-based browsers, such as Edge or Chrome, an **Add** button appears within the URL bar. After the user selects the **Add** button, they receive a confirmation dialog:

On iOS, visitors can install the PWA using Safari's **Share** button and its **Add to Homescreen** option. On Chrome for Android, users should select the **Menu** button in the upper-right corner, followed by **Add to Home screen**.

Once installed, the app appears in its own window without an address bar:

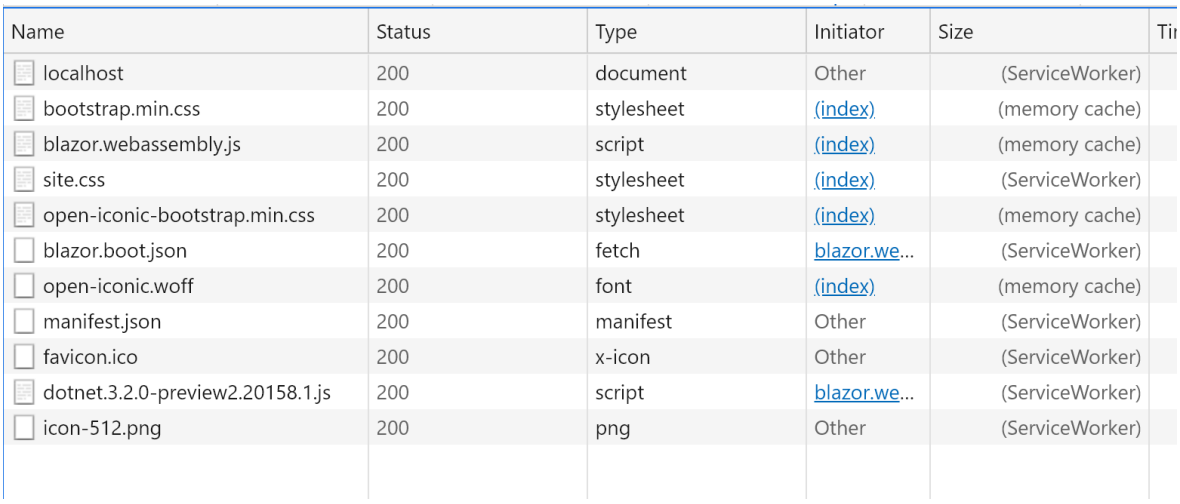
To customize the window's title, color scheme, icon, or other details, see the `manifest.json` file in the project's `wwwroot` directory. The schema of this file is defined by web standards. For more information, see MDN web docs: Web App Manifest.

Offline support



Apps created using the PWA template option have support for running offline. A user must first visit the app while they're online. The browser automatically downloads and caches all of the resources required to operate offline.

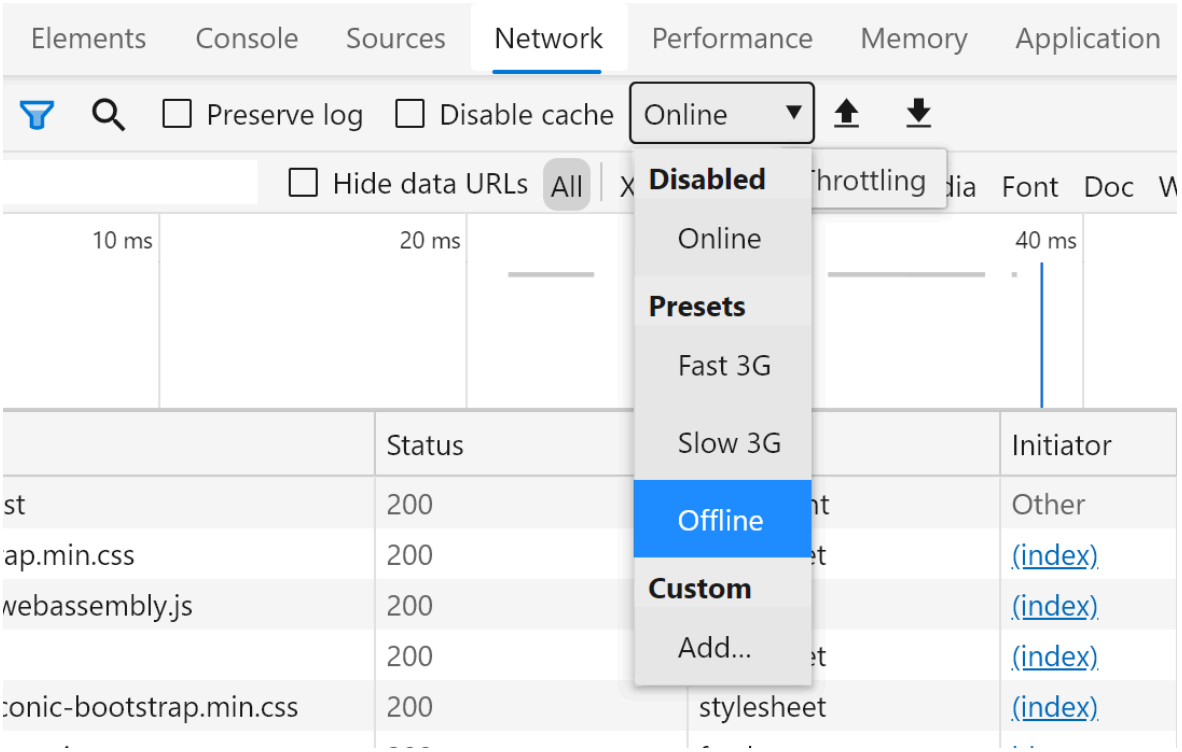
> **ⓘ Important**
>
> Development support would interfere with the usual development cycle of making changes and testing them. Therefore, offline support is only enabled for *published* apps.



> **⚠ Warning**
>
> If you intend to distribute an offline-enabled PWA, there are several important warnings and caveats. These scenarios are inherent to offline PWAs and not specific to Blazor. Be sure to read and understand these caveats before making assumptions about how your offline-enabled app works.

To see how offline support works:

1. Publish the app. For more information, see Host and deploy ASP.NET Core Blazor.
2. Deploy the app to a server that supports HTTPS, and access the app in a browser at its secure HTTPS address.
3. Open the browser's dev tools and verify that a *Service Worker* is registered for the host on the **Application** tab:



4. Reload the page and examine the **Network** tab. **Service Worker** or **memory cache** are listed as the sources for all of the page's assets:

Name	Status	Type	Initiator	Size	Ti
localhost	200	document	Other	(ServiceWorker)	
bootstrap.min.css	200	stylesheet	(index)	(memory cache)	
blazor.webassembly.js	200	script	(index)	(memory cache)	
site.css	200	stylesheet	(index)	(ServiceWorker)	
open-iconic-bootstrap.min.css	200	stylesheet	(index)	(memory cache)	
blazor.boot.json	200	fetch	blazor.we...	(ServiceWorker)	
open-iconic.woff	200	font	(index)	(memory cache)	
manifest.json	200	manifest	Other	(ServiceWorker)	
favicon.ico	200	x-icon	Other	(ServiceWorker)	
dotnet.3.2.0-preview2.20158.1.js	200	script	blazor.we...	(ServiceWorker)	
icon-512.png	200	png	Other	(ServiceWorker)	

5. To verify that the browser isn't dependent on network access to load the app, either:
   - Shut down the web server and see how the app continues to function normally, which includes page reloads. Likewise, the app continues to function normally when there's a slow network connection.
   - Instruct the browser to simulate offline mode in the **Network** tab:

Offline support using a service worker is a web standard, not specific to Blazor. For more information on service workers, see MDN web docs: Service Worker API. To learn more about common usage patterns for service workers, see Google Web: The Service Worker Lifecycle.

Blazor's PWA template produces two service worker files:

- `wwwroot/service-worker.js`, which is used during development.
- `wwwroot/service-worker.published.js`, which is used after the app is published.

To share logic between the two service worker files, consider the following approach:

- Add a third JavaScript file to hold the common logic.
- Use self.importScripts to load the common logic into both service worker files.

Cache-first fetch strategy

The built-in `service-worker.published.js` service worker resolves requests using a *cache-first* strategy. This means that the service worker prefers to return cached content, regardless of whether the user has network access or newer content is available on the server.

The cache-first strategy is valuable because:

- **It ensures reliability.** Network access isn't a boolean state. A user isn't simply online or offline:

    - The user's device may assume it's online, but the network might be so slow as to be impractical to wait for.
    - The network might return invalid results for certain URLs, such as when there's a captive WIFI portal that's currently blocking or redirecting certain requests.

    This is why the browser's `navigator.onLine` API isn't reliable and shouldn't be depended upon.

- **It ensures correctness.** When building a cache of offline resources, the service worker uses content hashing to guarantee it has fetched a complete and self-consistent snapshot of resources at a single instant in time. This cache is then used as an atomic unit. There's no point asking the network for newer resources, since the only versions required are the ones already cached. Anything else risks inconsistency and incompatibility (for example, trying to use versions of .NET assemblies that weren't compiled together).

If you must prevent the browser from fetching `service-worker-assets.js` from its HTTP cache, for example to resolve temporary integrity check failures when deploying a new version of the service worker, update the service worker registration in `wwwroot/index.html` with updateViaCache set to 'none':

HTML

```
<script>
  navigator.serviceWorker.register('/service-worker.js', {updateViaCache:
'none'});
</script>
```

Background updates

As a mental model, you can think of an offline-first PWA as behaving like a mobile app that can be installed. The app starts up immediately regardless of network connectivity, but the installed app logic comes from a point-in-time snapshot that might not be the latest version.

The Blazor PWA template produces apps that automatically try to update themselves in the background whenever the user visits and has a working network connection. The way this works is as follows:

- During compilation, the project generates a *service worker assets manifest*, which is named `service-worker-assets.js`. The manifest lists all the static resources that the app requires to function offline, such as .NET assemblies, JavaScript files, and

CSS, including their content hashes. The resource list is loaded by the service worker so that it knows which resources to cache.

- Each time the user visits the app, the browser re-requests `service-worker.js` and `service-worker-assets.js` in the background. The files are compared byte-for-byte with the existing installed service worker. If the server returns changed content for either of these files, the service worker attempts to install a new version of itself.
- When installing a new version of itself, the service worker creates a new, separate cache for offline resources and starts populating the cache with resources listed in `service-worker-assets.js`. This logic is implemented in the `onInstall` function inside `service-worker.published.js`.
- The process completes successfully when all of the resources are loaded without error and all content hashes match. If successful, the new service worker enters a *waiting for activation* state. As soon as the user closes the app (no remaining app tabs or windows), the new service worker becomes *active* and is used for subsequent app visits. The old service worker and its cache are deleted.
- If the process doesn't complete successfully, the new service worker instance is discarded. The update process is attempted again on the user's next visit, when hopefully the client has a better network connection that can complete the requests.

Customize this process by editing the service worker logic. None of the preceding behavior is specific to Blazor but is merely the default experience provided by the PWA template option. For more information, see MDN web docs: Service Worker API.

How requests are resolved

As described in the Cache-first fetch strategy section, the default service worker uses a *cache-first* strategy, meaning that it tries to serve cached content when available. If there is no content cached for a certain URL, for example when requesting data from a backend API, the service worker falls back on a regular network request. The network request succeeds if the server is reachable. This logic is implemented inside `onFetch` function within `service-worker.published.js`.

If the app's Razor components rely on requesting data from backend APIs and you want to provide a friendly user experience for failed requests due to network unavailability, implement logic within the app's components. For example, use try/catch around HttpClient requests.

Support server-rendered pages

Consider what happens when the user first navigates to a URL such as `/counter` or any other deep link in the app. In these cases, you don't want to return content cached as `/counter`, but instead need the browser to load the content cached as `/index.html` to start up your Blazor WebAssembly app. These initial requests are known as *navigation* requests, as opposed to:

- `subresource` requests for images, stylesheets, or other files.
- `fetch/XHR` requests for API data.

The default service worker contains special-case logic for navigation requests. The service worker resolves the requests by returning the cached content for `/index.html`, regardless of the requested URL. This logic is implemented in the `onFetch` function inside `service-worker.published.js`.

If your app has certain URLs that must return server-rendered HTML, and not serve `/index.html` from the cache, then you need to edit the logic in your service worker. If all URLs containing `/Identity/` need to be handled as regular online-only requests to the server, then modify `service-worker.published.js` `onFetch` logic. Locate the following code:

JavaScript

```
const shouldServeIndexHtml = event.request.mode === 'navigate';
```

Change the code to the following:

JavaScript

```
const shouldServeIndexHtml = event.request.mode === 'navigate'
  && !event.request.url.includes('/Identity/');
```

If you don't do this, then regardless of network connectivity, the service worker intercepts requests for such URLs and resolves them using `/index.html`.

Add additional endpoints for external authentication providers to the check. In the following example, `/signin-google` for Google authentication is added to the check:

JavaScript

```
const shouldServeIndexHtml = event.request.mode === 'navigate'
  && !event.request.url.includes('/Identity/')
  && !event.request.url.includes('/signin-google');
```

No action is required for the `Development` environment, where content is always fetched from the network.

Control asset caching

If your project defines the `ServiceWorkerAssetsManifest` MSBuild property, Blazor's build tooling generates a service worker assets manifest with the specified name. The default PWA template produces a project file containing the following property:

XML

```
<ServiceWorkerAssetsManifest>service-worker-
assets.js</ServiceWorkerAssetsManifest>
```

The file is placed in the `wwwroot` output directory, so the browser can retrieve this file by requesting `/service-worker-assets.js`. To see the contents of this file, open `/bin/Debug/{TARGET FRAMEWORK}/wwwroot/service-worker-assets.js` in a text editor. However, don't edit the file, as it's regenerated on each build.

The manifest lists:

- Any Blazor-managed resources, such as .NET assemblies and the .NET WebAssembly runtime files required to function offline.
- All resources for publishing to the app's `wwwroot` directory, such as images, stylesheets, and JavaScript files, including static web assets supplied by external projects and NuGet packages.

You can control which of these resources are fetched and cached by the service worker by editing the logic in `onInstall` in `service-worker.published.js`. The service worker fetches and caches files matching typical web file name extensions such as `.html`, `.css`, `.js`, and `.wasm`, plus file types specific to Blazor WebAssembly, such as `.pdb` files (all versions) and `.dll` files (ASP.NET Core in .NET 7 or earlier).

To include additional resources that aren't present in the app's `wwwroot` directory, define extra MSBuild `ItemGroup` entries, as shown in the following example:

XML

```
<ItemGroup>
  <ServiceWorkerAssetsManifestItem Include="MyDirectory\AnotherFile.json"
    RelativePath="MyDirectory\AnotherFile.json"
AssetUrl="files/AnotherFile.json" />
</ItemGroup>
```

The `AssetUrl` metadata specifies the base-relative URL that the browser should use when fetching the resource to cache. This can be independent of its original source file name on disk.

> **ⓘ Important**
>
> Adding a `ServiceWorkerAssetsManifestItem` doesn't cause the file to be published in the app's `wwwroot` directory. The publish output must be controlled separately. The `ServiceWorkerAssetsManifestItem` only causes an additional entry to appear in the service worker assets manifest.

Push notifications

Like any other PWA, a Blazor WebAssembly PWA can receive push notifications from a backend server. The server can send push notifications at any time, even when the user isn't actively using the app. For example, push notifications can be sent when a different user performs a relevant action.

The mechanism for sending a push notification is entirely independent of Blazor WebAssembly, since it's implemented by the backend server which can use any technology. If you want to send push notifications from an ASP.NET Core server, consider using a technique similar to the approach taken in the Blazing Pizza workshop.

The mechanism for receiving and displaying a push notification on the client is also independent of Blazor WebAssembly, since it's implemented in the service worker JavaScript file. For an example, see the approach used in the Blazing Pizza workshop.

Caveats for offline PWAs

Not all apps should attempt to support offline use. Offline support adds significant complexity, while not always being relevant for the use cases required.

Offline support is usually relevant only:

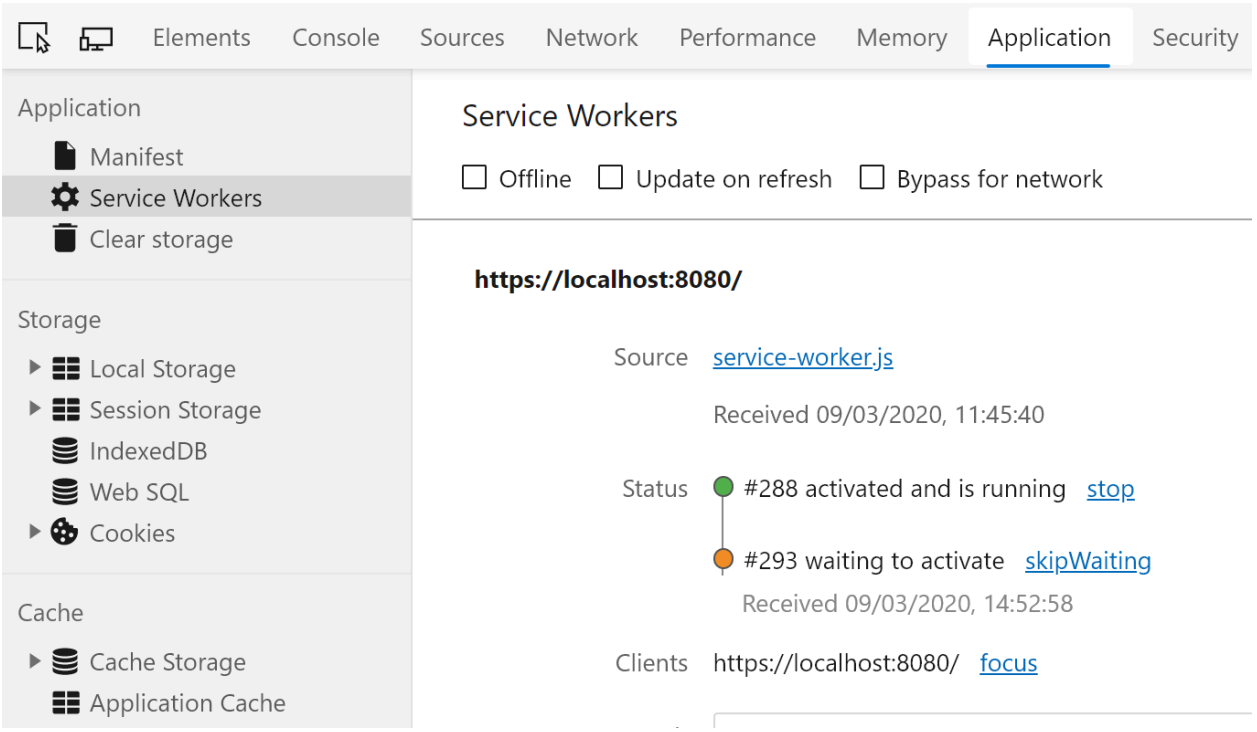
- If the primary data store is local to the browser. For example, the approach is relevant in an app with a UI for an IoT device that stores data in `localStorage` or IndexedDB.
- If the app performs a significant amount of work to fetch and cache the backend API data relevant to each user so that they can navigate through the data offline. If

the app must support editing, a system for tracking changes and synchronizing data with the backend must be built.
- If the goal is to guarantee that the app loads immediately regardless of network conditions. Implement a suitable user experience around backend API requests to show the progress of requests and behave gracefully when requests fail due to network unavailability.

Additionally, offline-capable PWAs must deal with a range of additional complications. Developers should carefully familiarize themselves with the caveats in the following sections.

Offline support only when published

During development you typically want to see each change reflected immediately in the browser without going through a background update process. Therefore, Blazor's PWA template enables offline support only when published.



When building an offline-capable app, it's not enough to test the app in the `Development` environment. You must test the app in its published state to understand how it responds to different network conditions.

Update completion after user navigation away from app

Updates don't complete until the user has navigated away from the app in all tabs. As explained in the Background updates section, after you deploy an update to the app, the browser fetches the updated service worker files to begin the update process.

What surprises many developers is that, even when this update completes, it doesn't take effect until the user has navigated away in all tabs. It isn't sufficient to refresh the tab displaying the app, even if it's the only tab displaying the app. Until your app is completely closed, the new service worker remains in the *waiting to activate* status. This isn't specific to Blazor, but rather is a standard web platform behavior.

This commonly troubles developers who are trying to test updates to their service worker or offline cached resources. If you check in the browser's developer tools, you may see something like the following:

For as long as the list of "clients," which are tabs or windows displaying your app, is nonempty, the worker continues waiting. The reason service workers do this is to guarantee consistency. Consistency means that all resources are fetched from the same atomic cache.

When testing changes, you may find it convenient to select the "skipWaiting" link as shown in the preceding screenshot, then reload the page. You can automate this for all users by coding your service worker to skip the "waiting" phase and immediately activate on update. If you skip the waiting phase, you're giving up the guarantee that resources are always fetched consistently from the same cache instance.

Users may run any historical version of the app

Web developers habitually expect that users only run the latest deployed version of their web app, since that's normal within the traditional web distribution model. However, an offline-first PWA is more akin to a native mobile app, where users aren't necessarily running the latest version.

As explained in the Background updates section, after you deploy an update to your app, each existing user continues to use a previous version for at least one further visit because the update occurs in the background and isn't activated until the user thereafter navigates away. Plus, the previous version being used isn't necessarily the previous one you deployed. The previous version can be *any* historical version, depending on when the user last completed an update.

This can be an issue if the frontend and backend parts of your app require agreement about the schema for API requests. You must not deploy backward-incompatible API

schema changes until you can be sure that all users have upgraded. Alternatively, block users from using incompatible older versions of the app. This scenario requirement is the same as for native mobile apps. If you deploy a breaking change in server APIs, the client app is broken for users who haven't yet updated.

If possible, don't deploy breaking changes to your backend APIs. If you must do so, consider using standard Service Worker APIs such as ServiceWorkerRegistration to determine whether the app is up-to-date, and if not, to prevent usage.

Interference with server-rendered pages

As described in the Support server-rendered pages section, if you want to bypass the service worker's behavior of returning `/index.html` contents for all navigation requests, edit the logic in your service worker.

All service worker asset manifest contents are cached

As described in the Control asset caching section, the file `service-worker-assets.js` is generated during build and lists all assets the service worker should fetch and cache.

Since this list includes everything emitted to `wwwroot`, including content supplied by external packages and projects, you must be careful not to put too much content there. If the `wwwroot` directory contains millions of images, the service worker tries to fetch and cache them all, consuming excessive bandwidth and most likely not completing successfully.

Implement arbitrary logic to control which subset of the manifest's contents should be fetched and cached by editing the `onInstall` function in `service-worker.published.js`.

Interaction with authentication

The PWA template can be used in conjunction with authentication. An offline-capable PWA can also support authentication when the user has initial network connectivity.

When a user doesn't have network connectivity, they can't authenticate or obtain access tokens. Attempting to visit the login page without network access results in a "network error" message. You must design a UI flow that allows the user perform useful tasks while offline without attempting to authenticate the user or obtain access tokens. Alternatively, you can design the app to gracefully fail when the network isn't available. If the app can't be designed to handle these scenarios, you might not want to enable offline support.

When an app that's designed for online and offline use is online again:

- The app might need to provision a new access token.
- The app must detect if a different user is signed into the service so that it can apply operations to the user's account that were made while they were offline.

To create an offline PWA app that interacts with authentication:

- Replace the AccountClaimsPrincipalFactory<TAccount> with a factory that stores the last signed-in user and uses the stored user when the app is offline.
- Enqueue operations while the app is offline and apply them when the app returns online.
- During sign out, clear the stored user.

The CarChecker sample app demonstrates the preceding approaches. See the following parts of the app:

- `OfflineAccountClaimsPrincipalFactory` (`Client/Data/OfflineAccountClaimsPrincipalFactory.cs`)
- `LocalVehiclesStore` (`Client/Data/LocalVehiclesStore.cs`)
- `LoginStatus` component (`Client/Shared/LoginStatus.razor`)

Host and deploy ASP.NET Core Blazor

Article • 10/08/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to host and deploy Blazor apps.

Publish the app

Apps are published for deployment in Release configuration.

Visual Studio

1. Select the **Publish {APPLICATION}** command from the **Build** menu, where the `{APPLICATION}` placeholder the app's name.
2. Select the *publish target*. To publish locally, select **Folder**.
3. Accept the default location in the **Choose a folder** field or specify a different location. Select the **`Publish`** button.

Publishing the app triggers a restore of the project's dependencies and builds the project before creating the assets for deployment. As part of the build process, unused methods and assemblies are removed to reduce app download size and load times.

Publish locations:

- Blazor Web App: The app is published into the `/bin/Release/{TARGET FRAMEWORK}/publish` folder. Deploy the contents of the `publish` folder to the host.
- Blazor WebAssembly: The app is published into the `bin\Release\net8.0\browser-wasm\publish\` folder. To deploy the app as a static site, copy the contents of the `wwwroot` folder to the static site host.

The `{TARGET FRAMEWORK}` in the preceding paths is the target framework (for example, `net8.0`).

IIS

To host a Blazor app in IIS, see the following resources:

- IIS hosting
  - Publish an ASP.NET Core app to IIS
  - Host ASP.NET Core on Windows with IIS
- Host and deploy ASP.NET Core server-side Blazor apps: Server apps running on IIS, including IIS with Azure Virtual Machines (VMs) running Windows OS and Azure App Service.
- Host and deploy ASP.NET Core Blazor WebAssembly: Includes additional guidance for Blazor WebAssembly apps hosted on IIS, including static site hosting, custom `web.config` files, URL rewriting, sub-apps, compression, and Azure Storage static file hosting.
- IIS sub-application hosting
  - Follow the guidance in the App base path section for the Blazor app prior to publishing the app. The examples use an app base path of `/CoolApp` and show how to obtain the base path from app settings or other configuration providers.
  - Follow the sub-application configuration guidance in Advanced configuration. The sub-app's folder path under the root site becomes the virtual path of the sub-app. For an app base path of `/CoolApp`, the Blazor app is placed in a folder named `CoolApp` under the root site and the sub-app takes on a virtual path of `/CoolApp`.

Sharing an app pool among ASP.NET Core apps isn't supported, including for Blazor apps. Use one app pool per app when hosting with IIS, and avoid the use of IIS's virtual directories for hosting multiple apps.

App base path

The *app base path* is the app's root URL path. Successful routing in Blazor apps requires framework configuration for any root URL path that isn't at the default app base path `/`.

Consider the following ASP.NET Core app and Blazor sub-app:

- The ASP.NET Core app is named `MyApp`:
  - The app physically resides at `d:/MyApp`.
  - Requests are received at `https://www.contoso.com/{MYAPP RESOURCE}`.
- A Blazor app named `CoolApp` is a sub-app of `MyApp`:
  - The sub-app physically resides at `d:/MyApp/CoolApp`.
  - Requests are received at `https://www.contoso.com/CoolApp/{COOLAPP RESOURCE}`.

Without specifying additional configuration for `CoolApp`, the sub-app in this scenario has no knowledge of where it resides on the server. For example, the app can't construct correct relative URLs to its resources without knowing that it resides at the relative URL path `/CoolApp/`. This scenario also applies in various hosting and reverse proxy scenarios when an app isn't hosted at a root URL path.

Background

An anchor tag's destination (href) can be composed with either of two endpoints:

- Absolute locations that include a scheme (defaults to the page's scheme if omitted), host, port, and path or just a forward slash (`/`) followed by the path.

  Examples: `https://example.com/a/b/c` or `/a/b/c`

- Relative locations that contain just a path and do not start with a forward slash (`/`). These are resolved relative to the current document URL or the `<base>` tag's value, if specified.

  Example: `a/b/c`

The presence of a trailing slash (`/`) in a configured app base path is significant to compute the base path for URLs of the app. For example, `https://example.com/a` has a base path of `https://example.com/`, while `https://example.com/a/` with a trailing slash has a base path of `https://example.com/a`.

There are three sources of links that pertain to Blazor in ASP.NET Core apps:

- URLs in Razor components (`.razor`) are typically relative.
- URLs in scripts, such as the Blazor scripts (`blazor.*.js`), are relative to the document.

If you're rendering a Blazor app from different documents (for example, `/Admin/B/C/` and `/Admin/D/E/`), you must take the app base path into account, or the base path is different when the app renders in each document and the resources are fetched from the wrong URLs.

There are two approaches to deal with the challenge of resolving relative links correctly:

- Map the resources dynamically using the document they were rendered on as the root.
- Set a consistent base path for the document and map the resources under that base path.

The first option is more complicated and isn't the most typical approach, as it makes navigation different for each document. Consider the following example for rendering a page `/Something/Else`:

- Rendered under `/Admin/B/C/`, the page is rendered with a path of `/Admin/B/C/Something/Else`.
- Rendered under `/Admin/D/E/`, the page is rendered ***at the same path*** of `/Admin/B/C/Something/Else`.

Under the first approach, routing offers IDynamicEndpointMetadata and MatcherPolicy, which in combination can be the basis for implementing a completely dynamic solution that determines at runtime about how requests are routed.

For the second option, which is the usual approach taken, the app sets the base path in the document and maps the server endpoints to paths under the base. The following guidance adopts this approach.

Server-side Blazor

Map the SignalR hub of a server-side Blazor app by passing the path to MapBlazorHub in the `Program` file:

C#

```
app.MapBlazorHub("base/path");
```

The benefit of using MapBlazorHub is that you can map patterns, such as `"{tenant}"` and not just concrete paths.

You can also map the SignalR hub when the app is in a virtual folder with a branched middleware pipeline. In the following example, requests to `/base/path/` are handled by Blazor's SignalR hub:

C#

```
app.Map("/base/path/", subapp => {
    subapp.UsePathBase("/base/path/");
    subapp.UseRouting();
    subapp.UseEndpoints(endpoints => endpoints.MapBlazorHub());
});
```

Configure the `<base>` tag, per the guidance in the Configure the app base path section.

Standalone Blazor WebAssembly

In a standalone Blazor WebAssembly app, only the `<base>` tag is configured, per the guidance in the Configure the app base path section.

Configure the app base path

To provide configuration for the Blazor app's base path of `https://www.contoso.com/CoolApp/`, set the app base path (<base>), which is also called the relative root path.

By configuring the app base path, a component that isn't in the root directory can construct URLs relative to the app's root path. Components at different levels of the directory structure can build links to other resources at locations throughout the app. The app base path is also used to intercept selected hyperlinks where the `href` target of the link is within the app base path URI space. The Router component handles the internal navigation.

Place the the `<base>` tag in `<head>` markup (location of <head> content) before any elements with attribute values that are URLs, such as the `href` attributes of `<link>` elements.

In many hosting scenarios, the relative URL path to the app is the root of the app. In these default cases, the app's relative URL base path is `/` configured as `<base href="/" />` in <head> content.

> **Note**
>
> In some hosting scenarios, such as GitHub Pages and IIS sub-apps, the app base path must be set to the server's relative URL path of the app.

- In a server-side Blazor app, use ***either*** of the following approaches:
  - Option 1: Use the `<base>` tag to set the app's base path (location of <head> content):

    ```
    HTML
    ```

    ```
    <base href="/CoolApp/">
    ```

    The trailing slash is required.

- Option 2: Call UsePathBase ***first*** in the app's request processing pipeline (`Program.cs`) immediately after the WebApplicationBuilder is built (`builder.Build()`) to configure the base path for any following middleware that interacts with the request path:

  ```
  C#

  app.UsePathBase("/CoolApp");
  ```

  Calling UsePathBase is recommended when you also wish to run the Blazor Server app locally. For example, supply the launch URL in `Properties/launchSettings.json`:

  ```
  XML

  "launchUrl": "https://localhost:{PORT}/CoolApp",
  ```

  The `{PORT}` placeholder in the preceding example is the port that matches the secure port in the `applicationUrl` configuration path. The following example shows the full launch profile for an app at port 7279:

  ```
  XML

  "BlazorSample": {
    "commandName": "Project",
    "dotnetRunMessages": true,
    "launchBrowser": true,
    "applicationUrl": "https://localhost:7279;http://localhost:5279",
    "launchUrl": "https://localhost:7279/CoolApp",
    "environmentVariables": {
      "ASPNETCORE_ENVIRONMENT": "Development"
  }
  ```

  For more information on the `launchSettings.json` file, see Use multiple environments in ASP.NET Core. For additional information on Blazor app base paths and hosting, see <base href="/" /> or base-tag alternative for Blazor MVC integration (dotnet/aspnetcore #43191).

- Standalone Blazor WebAssembly (`wwwroot/index.html`):

  ```
  HTML

  <base href="/CoolApp/">
  ```

The trailing slash is required.

> **Note**
>
> When using WebApplication (see Migrate from ASP.NET Core 5.0 to 6.0), app.UseRouting must be called after UsePathBase so that the Routing Middleware can observe the modified path before matching routes. Otherwise, routes are matched before the path is rewritten by UsePathBase as described in the Middleware Ordering and Routing articles.

Don't prefix links throughout the app with a forward slash. Either avoid the use of a path segment separator or use dot-slash (`./`) relative path notation:

- ❌ Incorrect: `<a href="/account">`
- ✔️ Correct: `<a href="account">`
- ✔️ Correct: `<a href="./account">`

In Blazor WebAssembly web API requests with the HttpClient service, confirm that JSON helpers (HttpClientJsonExtensions) don't prefix URLs with a forward slash (`/`):

- ❌ Incorrect: `var rsp = await client.GetFromJsonAsync("/api/Account");`
- ✔️ Correct: `var rsp = await client.GetFromJsonAsync("api/Account");`

Don't prefix Navigation Manager relative links with a forward slash. Either avoid the use of a path segment separator or use dot-slash (`./`) relative path notation (`Navigation` is an injected NavigationManager):

- ❌ Incorrect: `Navigation.NavigateTo("/other");`
- ✔️ Correct: `Navigation.NavigateTo("other");`
- ✔️ Correct: `Navigation.NavigateTo("./other");`

In typical configurations for Azure/IIS hosting, additional configuration usually isn't required. In some non-IIS hosting and reverse proxy hosting scenarios, additional Static File Middleware configuration might be required:

- To serve static files correctly (for example, `app.UseStaticFiles("/CoolApp");`).
- To serve the Blazor script (`_framework/blazor.*.js`). For more information, see ASP.NET Core Blazor static files.

For a Blazor WebAssembly app with a non-root relative URL path (for example, `<base href="/CoolApp/">`), the app fails to find its resources *when run locally*. To overcome this problem during local development and testing, you can supply a *path base* argument

that matches the `href` value of the `<base>` tag at runtime. **Don't include a trailing slash.** To pass the path base argument when running the app locally, execute the `dotnet watch` (or `dotnet run`) command from the app's directory with the `--pathbase` option:

.NET CLI

```
dotnet watch --pathbase=/{RELATIVE URL PATH (no trailing slash)}
```

For a Blazor WebAssembly app with a relative URL path of `/CoolApp/` (`<base href="/CoolApp/">`), the command is:

.NET CLI

```
dotnet watch --pathbase=/CoolApp
```

If you prefer to configure the app's launch profile to specify the `pathbase` automatically instead of manually with `dotnet watch` (or `dotnet run`), set the `commandLineArgs` property in `Properties/launchSettings.json`. The following also configures the launch URL (`launchUrl`):

JSON

```
"commandLineArgs": "--pathbase=/{RELATIVE URL PATH (no trailing slash)}",
"launchUrl": "{RELATIVE URL PATH (no trailing slash)}",
```

Using `CoolApp` as the example:

JSON

```
"commandLineArgs": "--pathbase=/CoolApp",
"launchUrl": "CoolApp",
```

Using either `dotnet watch` (or `dotnet run`) with the `--pathbase` option or a launch profile configuration that sets the base path, the Blazor WebAssembly app responds locally at `http://localhost:port/CoolApp`.

For more information on the `launchSettings.json` file, see Use multiple environments in ASP.NET Core. For additional information on Blazor app base paths and hosting, see <base href="/" /> or base-tag alternative for Blazor MVC integration (dotnet/aspnetcore #43191).

Obtain the app base path from configuration

The following guidance explains how to obtain the path for the `<base>` tag from an app settings file for different environments.

Add the app settings file to the app. The following example is for the `Staging` environment (`appsettings.Staging.json`):

JSON

```
{
  "AppBasePath": "staging/"
}
```

In a server-side Blazor app, load the base path from configuration in <head> content:

razor

```
@inject IConfiguration Config

...

<head>
    ...
    <base href="/@(Config.GetValue<string>("AppBasePath"))" />
    ...
</head>
```

Alternatively, a server-side app can obtain the value from configuration for UsePathBase. Place the following code ***first*** in the app's request processing pipeline (`Program.cs`) immediately after the WebApplicationBuilder is built (`builder.Build()`). The following example uses the configuration key `AppBasePath`:

C#

```
app.UsePathBase($"/{app.Configuration.GetValue<string>("AppBasePath")}");
```

In a client-side Blazor WebAssembly app:

- Remove the `<base>` tag from `wwwroot/index.html`:

  diff

  ```
  - <base href="..." />
  ```

- Supply the app base path via a HeadContent component in the `App` component (`App.razor`):

  ```razor
  @inject IConfiguration Config

  ...

  <HeadContent>
      <base href="/@(Config.GetValue<string>("AppBasePath"))" />
  </HeadContent>
  ```

If there's no configuration value to load, for example in non-staging environments, the preceding `href` resolves to the root path `/`.

The examples in this section focus on supplying the app base path from app settings, but the approach of reading the path from IConfiguration is valid for any configuration provider. For more information, see the following resources:

- ASP.NET Core Blazor configuration
- Configuration in ASP.NET Core

Blazor Server `MapFallbackToPage` configuration

This section only applies to Blazor Server apps. MapFallbackToPage isn't supported in Blazor Web Apps and Blazor WebAssembly apps.

In scenarios where an app requires a separate area with custom resources and Razor components:

- Create a folder within the app's `Pages` folder to hold the resources. For example, an administrator section of an app is created in a new folder named `Admin` (`Pages/Admin`).

- Create a root page (`_Host.cshtml`) for the area. For example, create a `Pages/Admin/_Host.cshtml` file from the app's main root page (`Pages/_Host.cshtml`). Don't provide an `@page` directive in the Admin `_Host` page.

- Add a layout to the area's folder (for example, `Pages/Admin/_Layout.razor`). In the layout for the separate area, set the `<base>` tag `href` to match the area's folder (for example, `<base href="/Admin/" />`). For demonstration purposes, add `~/` to the static resources in the page. For example:

    - `~/css/bootstrap/bootstrap.min.css`
    - `~/css/site.css`
    - `~/BlazorSample.styles.css` (the example app's namespace is `BlazorSample`)
    - `~/_framework/blazor.server.js` (Blazor script)

- If the area should have its own static asset folder, add the folder and specify its location to Static File Middleware in `Program.cs` (for example, `app.UseStaticFiles("/Admin/wwwroot")`).

- Razor components are added to the area's folder. At a minimum, add an `Index` component to the area folder with the correct `@page` directive for the area. For example, add a `Pages/Admin/Index.razor` file based on the app's default `Pages/Index.razor` file. Indicate the Admin area as the route template at the top of the file (`@page "/admin"`). Add additional components as needed. For example, `Pages/Admin/Component1.razor` with an `@page` directive and route template of `@page "/admin/component1`.

- In `Program.cs`, call MapFallbackToPage for the area's request path immediately before the fallback root page path to the `_Host` page:

  C#

```
...
app.UseRouting();

app.MapBlazorHub();
app.MapFallbackToPage("~/Admin/{*clientroutes:nonfile}",
"/Admin/_Host");
app.MapFallbackToPage("/_Host");

app.Run();
```

Deployment

For deployment guidance, see the following topics:

- Host and deploy ASP.NET Core Blazor WebAssembly
- Host and deploy ASP.NET Core server-side Blazor apps

Host and deploy server-side Blazor apps

Article • 10/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to host and deploy server-side Blazor apps (Blazor Web Apps and Blazor Server apps) using ASP.NET Core.

Host configuration values

Server-side Blazor apps can accept Generic Host configuration values.

Deployment

Using a server-side hosting model, Blazor is executed on the server from within an ASP.NET Core app. UI updates, event handling, and JavaScript calls are handled over a SignalR connection.

A web server capable of hosting an ASP.NET Core app is required. Visual Studio includes a server-side app project template. For more information on Blazor project templates, see ASP.NET Core Blazor project structure.

Publish an app in Release configuration and deploy the contents of the `bin/Release/{TARGET FRAMEWORK}/publish` folder, where the `{TARGET FRAMEWORK}` placeholder is the target framework.

Scalability

When considering the scalability of a single server (scale up), the memory available to an app is likely the first resource that the app exhausts as user demands increase. The available memory on the server affects the:

- Number of active circuits that a server can support.

- UI latency on the client.

For guidance on building secure and scalable server-side Blazor apps, see the following resources:

- Threat mitigation guidance for ASP.NET Core Blazor static server-side rendering
- Threat mitigation guidance for ASP.NET Core Blazor interactive server-side rendering

Each circuit uses approximately 250 KB of memory for a minimal *Hello World*-style app. The size of a circuit depends on the app's code and the state maintenance requirements associated with each component. We recommend that you measure resource demands during development for your app and infrastructure, but the following baseline can be a starting point in planning your deployment target: If you expect your app to support 5,000 concurrent users, consider budgeting at least 1.3 GB of server memory to the app (or ~273 KB per user).

SignalR configuration

SignalR's hosting and scaling conditions apply to Blazor apps that use SignalR.

For more information on SignalR in Blazor apps, including configuration guidance, see ASP.NET Core Blazor SignalR guidance.

Transports

Blazor works best when using WebSockets as the SignalR transport due to lower latency, better reliability, and improved security. Long Polling is used by SignalR when WebSockets isn't available or when the app is explicitly configured to use Long Polling.

A console warning appears if Long Polling is utilized:

> Failed to connect via WebSockets, using the Long Polling fallback transport. This may be due to a VPN or proxy blocking the connection.

Global deployment and connection failures

Recommendations for global deployments to geographical data centers:

- Deploy the app to the regions where most of the users reside.
- Take into consideration the increased latency for traffic across continents. To control the appearance of the reconnection UI, see ASP.NET Core Blazor SignalR

guidance.
- Consider using the Azure SignalR Service.

Azure App Service

Hosting on Azure App Service requires configuration for WebSockets and session affinity, also called Application Request Routing (ARR) affinity.

> ⓘ **Note**
>
> A Blazor app on Azure App Service doesn't require Azure SignalR Service.

Enable the following for the app's registration in Azure App Service:

- WebSockets to allow the WebSockets transport to function. The default setting is **Off**.
- Session affinity to route requests from a user back to the same App Service instance. The default setting is **On**.

1. In the Azure portal, navigate to the web app in **App Services**.
2. Open **Settings** > **Configuration**.
3. Set **Web sockets** to **On**.
4. Verify that **Session affinity** is set to **On**.

Azure SignalR Service

The optional Azure SignalR Service works in conjunction with the app's SignalR hub for scaling up a server-side app to a large number of concurrent connections. In addition, the service's global reach and high-performance data centers significantly aid in reducing latency due to geography.

The service isn't required for Blazor apps hosted in Azure App Service or Azure Container Apps but can be helpful in other hosting environments:

- To facilitate connection scale out.
- Handle global distribution.

> ⓘ **Note**
>
> Stateful reconnect (WithStatefulReconnect) was released with .NET 8 but isn't currently supported for the Azure SignalR Service. For more information, see

Stateful Reconnect Support? (Azure/azure-signalr #1878) .

In the event that the app uses Long Polling or falls back to Long Polling instead of WebSockets, you may need to configure the maximum poll interval (`MaxPollIntervalInSeconds`, default: 5 seconds, limit: 1-300 seconds), which defines the maximum poll interval allowed for Long Polling connections in the Azure SignalR Service. If the next poll request doesn't arrive within the maximum poll interval, the service closes the client connection.

For guidance on how to add the service as a dependency to a production deployment, see Publish an ASP.NET Core SignalR app to Azure App Service.

For more information, see:

- Azure SignalR Service
- What is Azure SignalR Service?
- ASP.NET Core SignalR production hosting and scaling
- Publish an ASP.NET Core SignalR app to Azure App Service

Azure Container Apps

For a deeper exploration of scaling server-side Blazor apps on the Azure Container Apps service, see Scaling ASP.NET Core Apps on Azure. The tutorial explains how to create and integrate the services required to host apps on Azure Container Apps. Basic steps are also provided in this section.

1. Configure Azure Container Apps service for session affinity by following the guidance in Session Affinity in Azure Container Apps (Azure documentation).

2. The ASP.NET Core Data Protection (DP) service must be configured to persist keys in a centralized location that all container instances can access. The keys can be stored in Azure Blob Storage and protected with Azure Key Vault. The DP service uses the keys to deserialize Razor components. To configure the DP service to use Azure Blob Storage and Azure Key Vault, reference the following NuGet packages:

    - Azure.Identity : Provides classes to work with the Azure identity and access management services.
    - Microsoft.Extensions.Azure : Provides helpful extension methods to perform core Azure configurations.
    - Azure.Extensions.AspNetCore.DataProtection.Blobs : Allows storing ASP.NET Core Data Protection keys in Azure Blob Storage so that keys can be shared across several instances of a web app.

- Azure.Extensions.AspNetCore.DataProtection.Keys: Enables protecting keys at rest using the Azure Key Vault Key Encryption/Wrapping feature.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

3. Update `Program.cs` with the following highlighted code:

```C#
using Azure.Identity;
using Microsoft.AspNetCore.DataProtection;
using Microsoft.Extensions.Azure;
var builder = WebApplication.CreateBuilder(args);
var BlobStorageUri = builder.Configuration["AzureURIs:BlobStorage"];
var KeyVaultURI = builder.Configuration["AzureURIs:KeyVault"];

builder.Services.AddRazorPages();
builder.Services.AddHttpClient();
builder.Services.AddServerSideBlazor();

builder.Services.AddAzureClientsCore();

builder.Services.AddDataProtection()
                .PersistKeysToAzureBlobStorage(new Uri(BlobStorageUri),
                                               new
DefaultAzureCredential())
                .ProtectKeysWithAzureKeyVault(new Uri(KeyVaultURI),
                                               new
DefaultAzureCredential());
var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();
```

```
app.Run();
```

The preceding changes allow the app to manage the DP service using a centralized, scalable architecture. DefaultAzureCredential discovers the container app managed identity after the code is deployed to Azure and uses it to connect to blob storage and the app's key vault.

4. To create the container app managed identity and grant it access to blob storage and a key vault, complete the following steps:
   a. In the Azure Portal, navigate to the overview page of the container app.
   b. Select **Service Connector** from the left navigation.
   c. Select **+ Create** from the top navigation.
   d. In the **Create connection** flyout menu, enter the following values:

      - **Container**: Select the container app you created to host your app.
      - **Service type**: Select **Blob Storage**.
      - **Subscription**: Select the subscription that owns the container app.
      - **Connection name**: Enter a name of `scalablerazorstorage`.
      - **Client type**: Select **.NET** and then select **Next**.

   e. Select **System assigned managed identity** and select **Next**.
   f. Use the default network settings and select **Next**.
   g. After Azure validates the settings, select **Create**.

   Repeat the preceding settings for the key vault. Select the appropriate key vault service and key in the **Basics** tab.

IIS

When using IIS, enable:

- WebSockets on IIS.
- Session affinity with Application Request Routing.

For more information, see the guidance and external IIS resource cross-links in Publish an ASP.NET Core app to IIS.

Kubernetes

Create an ingress definition with the following Kubernetes annotations for session affinity :

YAML

```yaml
apiVersion: extensions/v1beta1
kind: Ingress
metadata:
  name: <ingress-name>
  annotations:
    nginx.ingress.kubernetes.io/affinity: "cookie"
    nginx.ingress.kubernetes.io/session-cookie-name: "affinity"
    nginx.ingress.kubernetes.io/session-cookie-expires: "14400"
    nginx.ingress.kubernetes.io/session-cookie-max-age: "14400"
```

Linux with Nginx

Follow the guidance for an ASP.NET Core SignalR app with the following changes:

- Change the `location` path from `/hubroute` (`location /hubroute { ... }`) to the root path `/` (`location / { ... }`).
- Remove the configuration for proxy buffering (`proxy_buffering off;`) because the setting only applies to Server-Sent Events (SSE), which aren't relevant to Blazor app client-server interactions.

For more information and configuration guidance, consult the following resources:

- ASP.NET Core SignalR production hosting and scaling
- Host ASP.NET Core on Linux with Nginx
- Configure ASP.NET Core to work with proxy servers and load balancers
- NGINX as a WebSocket Proxy
- WebSocket proxying
- Consult developers on non-Microsoft support forums:
  - Stack Overflow (tag: blazor)
  - ASP.NET Core Slack Team
  - Blazor Gitter

Linux with Apache

To host a Blazor app behind Apache on Linux, configure `ProxyPass` for HTTP and WebSockets traffic.

In the following example:

- Kestrel server is running on the host machine.
- The app listens for traffic on port 5000.

```
ProxyPreserveHost   On
ProxyPassMatch      ^/_blazor/(.*) http://localhost:5000/_blazor/$1
ProxyPass           /_blazor ws://localhost:5000/_blazor
ProxyPass           / http://localhost:5000/
ProxyPassReverse    / http://localhost:5000/
```

Enable the following modules:

```
a2enmod   proxy
a2enmod   proxy_wstunnel
```

Check the browser console for WebSockets errors. Example errors:

- Firefox can't establish a connection to the server at ws://the-domain-name.tld/_blazor?id=XXX
- Error: Failed to start the transport 'WebSockets': Error: There was an error with the transport.
- Error: Failed to start the transport 'LongPolling': TypeError: this.transport is undefined
- Error: Unable to connect to the server with any of the available transports. WebSockets failed
- Error: Cannot send data if the connection is not in the 'Connected' State.

For more information and configuration guidance, consult the following resources:

- Configure ASP.NET Core to work with proxy servers and load balancers
- Apache documentation
- Consult developers on non-Microsoft support forums:
  - Stack Overflow (tag: blazor)
  - ASP.NET Core Slack Team
  - Blazor Gitter

Measure network latency

JS interop can be used to measure network latency, as the following example demonstrates.

`MeasureLatency.razor`:

```
razor
```

```
@inject IJSRuntime JS

<h2>Measure Latency</h2>

@if (latency is null)
{
    <span>Calculating...</span>
}
else
{
    <span>@(latency.Value.TotalMilliseconds)ms</span>
}

@code {
    private DateTime startTime;
    private TimeSpan? latency;

    protected override async Task OnAfterRenderAsync(bool firstRender)
    {
        if (firstRender)
        {
            startTime = DateTime.UtcNow;
            var _ = await JS.InvokeAsync<string>("toString");
            latency = DateTime.UtcNow - startTime;
            StateHasChanged();
        }
    }
}
```

For a reasonable UI experience, we recommend a sustained UI latency of 250 ms or less.

Memory management

On the server, a new circuit is created for each user session. Each user session corresponds to rendering a single document in the browser. For example, multiple tabs create multiple sessions.

Blazor maintains a constant connection to the browser, called a *circuit*, that initiated the session. Connections can be lost at any time for any of several reasons, such as when the user loses network connectivity or abruptly closes the browser. When a connection is lost, Blazor has a recovery mechanism that places a limited number of circuits in a "disconnected" pool, giving clients a limited amount of time to reconnect and re-establish the session (default: 3 minutes).

After that time, Blazor releases the circuit and discards the session. From that point on, the circuit is eligible for garbage collection (GC) and is claimed when a collection for the circuit's GC generation is triggered. One important aspect to understand is that circuits

have a long lifetime, which means that most of the objects rooted by the circuit eventually reach Gen 2. As a result, you might not see those objects released until a Gen 2 collection happens.

Measure memory usage in general

Prerequisites:

- The app must be published in **Release** configuration. **Debug** configuration measurements aren't relevant, as the generated code isn't representative of the code used for a production deployment.
- The app must run without a debugger attached, as this might also affect the behavior of the app and spoil the results. In Visual Studio, start the app without debugging by selecting **Debug** > **Start Without Debugging** from the menu bar or `Ctrl`+`F5` using the keyboard.
- Consider the different types of memory to understand how much memory is actually used by .NET. Generally, developers inspect app memory usage in Task Manager on Windows OS, which typically offers an upper bound of the actual memory in use. For more information, consult the following articles:
  - .NET Memory Performance Analysis : In particular, see the section on Memory Fundamentals .
  - Work flow of diagnosing memory performance issues (three-part series) : Links to the three articles of the series are at the top of each article in the series.

Memory usage applied to Blazor

We compute the memory used by blazor as follows:

(**Active Circuits** × **Per-circuit Memory**) + (**Disconnected Circuits** × **Per-circuit Memory**)

The amount of memory a circuit uses and the maximum potential active circuits that an app can maintain is largely dependent on how the app is written. The maximum number of possible active circuits is roughly described by:

Maximum Available Memory / **Per-circuit Memory** = **Maximum Potential Active Circuits**

For a memory leak to occur in Blazor, the following must be true:

- The memory must be allocated by the framework, not the app. If you allocate a 1 GB array in the app, the app must manage the disposal of the array.
- The memory must not be actively used, which means the circuit isn't active and has been evicted from the disconnected circuits cache. If you have the maximum active

circuits running, running out of memory is a scale issue, not a memory leak.
- A garbage collection (GC) for the circuit's GC generation has run, but the garbage collector hasn't been able to claim the circuit because another object in the framework is holding a strong reference to the circuit.

In other cases, there's no memory leak. If the circuit is active (connected or disconnected), the circuit is still in use.

If a collection for the circuit's GC generation doesn't run, the memory isn't released because the garbage collector doesn't need to free the memory at that time.

If a collection for a GC generation runs and frees the circuit, you must validate the memory against the GC stats, not the process, as .NET might decide to keep the virtual memory active.

If the memory isn't freed, you must find a circuit that isn't either active or disconnected and that's rooted by another object in the framework. In any other case, the inability to free memory is an app issue in developer code.

Reduce memory usage

Adopt any of the following strategies to reduce an app's memory usage:

- Limit the total amount of memory used by the .NET process. For more information, see Runtime configuration options for garbage collection.
- Reduce the number of disconnected circuits.
- Reduce the time a circuit is allowed to be in the disconnected state.
- Trigger a garbage collection manually to perform a collection during downtime periods.
- Configure the garbage collection in Workstation mode, which aggressively triggers garbage collection, instead of Server mode.

Heap size for some mobile device browsers

When building a Blazor app that runs on the client and targets mobile device browsers, especially Safari on iOS, decreasing the maximum memory for the app with the MSBuild property `EmccMaximumHeapSize` may be required. For more information, see Host and deploy ASP.NET Core Blazor WebAssembly.

Additional actions and considerations

- Capture a memory dump of the process when memory demands are high and identify the objects are taking the most memory and where are those objects are rooted (what holds a reference to them).
- You can examine the statistics on how memory in your app is behaving using `dotnet-counters`. For more information see Investigate performance counters (dotnet-counters).
- Even when a GC is triggered, .NET holds on to the memory instead of returning it to the OS immediately, as it's likely that it will reuse the memory the near future. This avoids committing and decommitting memory constantly, which is expensive. You'll see this reflected if you use `dotnet-counters` because you'll see the GCs happen and the amount of used memory go down to 0 (zero), but you won't see the working set counter decrease, which is the sign that .NET is holding on to the memory to reuse it. For more information on project file (`.csproj`) settings to control this behavior, see Runtime configuration options for garbage collection.
- Server GC doesn't trigger garbage collections until it determines it's absolutely necessary to do so to avoid freezing your app and considers that your app is the only thing running on the machine, so it can use all the memory in the system. If the system has 50 GB, the garbage collector seeks to use the full 50 GB of available memory before it triggers a Gen 2 collection.
- For information on disconnected circuit retention configuration, see ASP.NET Core Blazor SignalR guidance.

Measuring memory

- Publish the app in Release configuration.
- Run a published version of the app.
- Don't attach a debugger to the running app.
- Does triggering a Gen 2 forced, compacting collection (`GC.Collect(2, GCCollectionMode.Aggressive | GCCollectionMode.Forced, blocking: true, compacting: true))` free the memory?
- Consider if your app is allocating objects on the large object heap.
- Are you testing the memory growth after the app is warmed up with requests and processing? Typically, there are caches that are populated when code executes for the first time that add a constant amount of memory to the footprint of the app.

Host and deploy ASP.NET Core Blazor WebAssembly

Article • 09/27/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to host and deploy Blazor WebAssembly using ASP.NET Core, Content Delivery Networks (CDN), file servers, and GitHub Pages.

With the Blazor WebAssembly hosting model:

- The Blazor app, its dependencies, and the .NET runtime are downloaded to the browser in parallel.
- The app is executed directly on the browser UI thread.

This article pertains to the deployment scenario where the Blazor app is placed on a static hosting web server or service, .NET isn't used to serve the Blazor app. This strategy is covered in the Standalone deployment section, which includes information on hosting a Blazor WebAssembly app as an IIS sub-app.

Subdomain and IIS sub-application hosting

Subdomain hosting doesn't require special configuration of the app. You ***don't*** need to configure the app base path (the `<base>` tag in `wwwroot/index.html`) to host the app at a subdomain.

IIS sub-application hosting ***does*** require you to set the app base path. For more information and cross-links to further guidance on IIS sub-application hosting, see Host and deploy ASP.NET Core Blazor.

Decrease maximum heap size for some mobile device browsers

When building a Blazor app that runs on the client (`.Client` project of a Blazor Web App or standalone Blazor WebAssembly app) and targets mobile device browsers, especially Safari on iOS, decreasing the maximum memory for the app with the MSBuild property `EmccMaximumHeapSize` may be required. The default value is 2,147,483,648 bytes, which may be too large and result in the app crashing if the app attempts to allocate more memory with the browser failing to grant it. The following example sets the value to 268,435,456 bytes in the `Program` file:

XML

```
<EmccMaximumHeapSize>268435456</EmccMaximumHeapSize>
```

For more information on Mono/WebAssembly MSBuild properties and targets, see WasmApp.Common.targets (dotnet/runtime GitHub repository).

Webcil packaging format for .NET assemblies

Webcil is a web-friendly packaging format for .NET assemblies designed to enable using Blazor WebAssembly in restrictive network environments. Webcil files use a standard WebAssembly wrapper, where the assemblies are deployed as WebAssembly files that use the standard `.wasm` file extension.

Webcil is the default packaging format when you publish a Blazor WebAssembly app. To disable the use of Webcil, set the following MSBuild property in the app's project file:

XML

```
<PropertyGroup>
  <WasmEnableWebcil>false</WasmEnableWebcil>
</PropertyGroup>
```

Customize how boot resources are loaded

Customize how boot resources are loaded using the `loadBootResource` API. For more information, see ASP.NET Core Blazor startup.

Compression

When a Blazor WebAssembly app is published, the output is statically compressed during publish to reduce the app's size and remove the overhead for runtime

compression. The following compression algorithms are used:

- Brotli (highest level)
- Gzip

Blazor relies on the host to serve the appropriate compressed files. When hosting a Blazor WebAssembly standalone app, additional work might be required to ensure that statically-compressed files are served:

- For IIS `web.config` compression configuration, see the IIS: Brotli and Gzip compression section.
- When hosting on static hosting solutions that don't support statically-compressed file content negotiation, consider configuring the app to fetch and decode Brotli compressed files:

Obtain the JavaScript Brotli decoder from the google/brotli GitHub repository. The minified decoder file is named `decode.min.js` and found in the repository's js folder.

> **Note**
>
> If the minified version of the `decode.js` script (`decode.min.js`) fails, try using the unminified version (`decode.js`) instead.

Update the app to use the decoder.

In the `wwwroot/index.html` file, set `autostart` to `false` on Blazor's `<script>` tag:

HTML

```
<script src="_framework/blazor.webassembly.js" autostart="false"></script>
```

After Blazor's `<script>` tag and before the closing `</body>` tag, add the following JavaScript code `<script>` block.

Blazor Web App:

HTML

```
<script type="module">
  import { BrotliDecode } from './decode.min.js';
  Blazor.start({
    webAssembly: {
      loadBootResource: function (type, name, defaultUri, integrity) {
        if (type !== 'dotnetjs' && location.hostname !== 'localhost' && type
!== 'configuration' && type !== 'manifest') {
```

```
          return (async function () {
            const response = await fetch(defaultUri + '.br', { cache: 'no-
cache' });
            if (!response.ok) {
              throw new Error(response.statusText);
            }
            const originalResponseBuffer = await response.arrayBuffer();
            const originalResponseArray = new
Int8Array(originalResponseBuffer);
            const decompressedResponseArray =
BrotliDecode(originalResponseArray);
            const contentType = type ===
              'dotnetwasm' ? 'application/wasm' : 'application/octet-
stream';
            return new Response(decompressedResponseArray,
              { headers: { 'content-type': contentType } });
          })();
        }
      }
    }
  });
</script>
```

Standalone Blazor WebAssembly:

HTML

```
<script type="module">
  import { BrotliDecode } from './decode.min.js';
  Blazor.start({
    loadBootResource: function (type, name, defaultUri, integrity) {
      if (type !== 'dotnetjs' && location.hostname !== 'localhost' && type
!== 'configuration') {
        return (async function () {
          const response = await fetch(defaultUri + '.br', { cache: 'no-
cache' });
          if (!response.ok) {
            throw new Error(response.statusText);
          }
          const originalResponseBuffer = await response.arrayBuffer();
          const originalResponseArray = new
Int8Array(originalResponseBuffer);
          const decompressedResponseArray =
BrotliDecode(originalResponseArray);
          const contentType = type ===
            'dotnetwasm' ? 'application/wasm' : 'application/octet-stream';
          return new Response(decompressedResponseArray,
            { headers: { 'content-type': contentType } });
        })();
      }
    }
```

```
  });
</script>
```

For more information on loading boot resources, see ASP.NET Core Blazor startup.

To disable compression, add the `CompressionEnabled` MSBuild property to the app's project file and set the value to `false`:

XML

```
<PropertyGroup>
  <CompressionEnabled>false</CompressionEnabled>
</PropertyGroup>
```

The `CompressionEnabled` property can be passed to the dotnet publish command with the following syntax in a command shell:

.NET CLI

```
dotnet publish -p:CompressionEnabled=false
```

Rewrite URLs for correct routing

Routing requests for page components in a Blazor WebAssembly app isn't as straightforward as routing requests in a Blazor Server app. Consider a Blazor WebAssembly app with two components:

- `Main.razor`: Loads at the root of the app and contains a link to the `About` component (`href="About"`).
- `About.razor`: `About` component.

When the app's default document is requested using the browser's address bar (for example, `https://www.contoso.com/`):

1. The browser makes a request.
2. The default page is returned, which is usually `index.html`.
3. `index.html` bootstraps the app.
4. Router component loads, and the Razor `Main` component is rendered.

In the Main page, selecting the link to the `About` component works on the client because the Blazor router stops the browser from making a request on the Internet to `www.contoso.com` for `About` and serves the rendered `About` component itself. All of the

requests for internal endpoints *within the Blazor WebAssembly app* work the same way: Requests don't trigger browser-based requests to server-hosted resources on the Internet. The router handles the requests internally.

If a request is made using the browser's address bar for `www.contoso.com/About`, the request fails. No such resource exists on the app's Internet host, so a *404 - Not Found* response is returned.

Because browsers make requests to Internet-based hosts for client-side pages, web servers and hosting services must rewrite all requests for resources not physically on the server to the `index.html` page. When `index.html` is returned, the app's Blazor router takes over and responds with the correct resource.

When deploying to an IIS server, you can use the URL Rewrite Module with the app's published `web.config` file. For more information, see the IIS section.

Standalone deployment

A *standalone deployment* serves the Blazor WebAssembly app as a set of static files that are requested directly by clients. Any static file server is able to serve the Blazor app.

Standalone deployment assets are published into either the `/bin/Release/{TARGET FRAMEWORK}/publish/wwwroot` or `bin\Release\{TARGET FRAMEWORK}\browser-wasm\publish\` folder (depending on the version of the .NET SDK in use), where the `{TARGET FRAMEWORK}` placeholder is the target framework.

Azure App Service

Blazor WebAssembly apps can be deployed to Azure App Services on Windows, which hosts the app on IIS.

Deploying a standalone Blazor WebAssembly app to Azure App Service for Linux isn't currently supported. We recommend hosting a standalone Blazor WebAssembly app using Azure Static Web Apps, which supports this scenario.

Azure Static Web Apps

Use one of the following approaches to deploy a Blazor WebAssembly app to Azure Static Web Apps:

- Deploy from Visual Studio
- Deploy from Visual Studio Code

- Deploy from GitHub

Deploy from Visual Studio

To deploy from Visual Studio, create a publish profile for Azure Static Web Apps:

1. Save any unsaved work in the project, as a Visual Studio restart might be required during the process.

2. In Visual Studio's **Publish** UI, select **Target** > **Azure** > **Specific Target** > **Azure Static Web Apps** to create a publish profile.

3. If the **Azure WebJobs Tools** component for Visual Studio isn't installed, a prompt appears to install the **ASP.NET and web development** component. Follow the prompts to install the tools using the Visual Studio Installer. Visual Studio closes and reopens automatically while installing the tools. After the tools are installed, start over at the first step to create the publish profile.

4. In the publish profile configuration, provide the **Subscription name**. Select an existing instance, or select **Create a new instance**. When creating a new instance in the Azure portal's **Create Static Web App** UI, set the **Deployment details** > **Source** to **Other**. Wait for the deployment to complete in the Azure portal before proceeding.

5. In the publish profile configuration, select the Azure Static Web Apps instance from the instance's resource group. Select **Finish** to create the publish profile. If Visual Studio prompts to install the Static Web Apps (SWA) CLI, install the CLI by following the prompts. The SWA CLI requires NPM/Node.js (Visual Studio documentation).

After the publish profile is created, deploy the app to the Azure Static Web Apps instance using the publish profile by selecting the **Publish** button.

Deploy from Visual Studio Code

To deploy from Visual Studio Code, see Quickstart: Build your first static site with Azure Static Web Apps.

Deploy from GitHub

To deploy from a GitHub repository, see Tutorial: Building a static web app with Blazor in Azure Static Web Apps.

IIS

IIS is a capable static file server for Blazor apps. To configure IIS to host Blazor, see Build a Static Website on IIS.

Published assets are created in the `/bin/Release/{TARGET FRAMEWORK}/publish` or `bin\Release\{TARGET FRAMEWORK}\browser-wasm\publish` folder, depending on which version of the SDK is used and where the `{TARGET FRAMEWORK}` placeholder is the target framework. Host the contents of the `publish` folder on the web server or hosting service.

web.config

When a Blazor project is published, a `web.config` file is created with the following IIS configuration:

- MIME types
- HTTP compression is enabled for the following MIME types:
  - `application/octet-stream`
  - `application/wasm`
- URL Rewrite Module rules are established:
  - Serve the sub-directory where the app's static assets reside (`wwwroot/{PATH REQUESTED}`).
  - Create SPA fallback routing so that requests for non-file assets are redirected to the app's default document in its static assets folder (`wwwroot/index.html`).

Use a custom `web.config`

To use a custom `web.config` file:

1. Place the custom `web.config` file in the project's root folder.
2. Publish the project. For more information, see Host and deploy ASP.NET Core Blazor.

If the SDK's `web.config` generation or transformation during publish either doesn't move the file to published assets in the `publish` folder or modifies the custom configuration in your custom `web.config` file, use any of the following approaches as needed to take full control of the process:

- If the SDK doesn't generate the file, for example, in a standalone Blazor WebAssembly app at `/bin/Release/{TARGET FRAMEWORK}/publish/wwwroot` or

`bin\Release\{TARGET FRAMEWORK}\browser-wasm\publish`, depending on which version of the SDK is used and where the `{TARGET FRAMEWORK}` placeholder is the target framework, set the `<PublishIISAssets>` property to `true` in the project file (`.csproj`). Usually for standalone WebAssembly apps, this is the only required setting to move a custom `web.config` file and prevent transformation of the file by the SDK.

XML

```
<PropertyGroup>
  <PublishIISAssets>true</PublishIISAssets>
</PropertyGroup>
```

- Disable the SDK's `web.config` transformation in the project file (`.csproj`):

  XML

  ```
  <PropertyGroup>
    <IsTransformWebConfigDisabled>true</IsTransformWebConfigDisabled>
  </PropertyGroup>
  ```

- Add a custom target to the project file (`.csproj`) to move a custom `web.config` file. In the following example, the custom `web.config` file is placed by the developer at the root of the project. If the `web.config` file resides elsewhere, specify the path to the file in `SourceFiles`. The following example specifies the `publish` folder with `$(PublishDir)`, but provide a path to `DestinationFolder` for a custom output location.

  XML

  ```
  <Target Name="CopyWebConfig" AfterTargets="Publish">
    <Copy SourceFiles="web.config" DestinationFolder="$(PublishDir)" />
  </Target>
  ```

Install the URL Rewrite Module

The URL Rewrite Module is required to rewrite URLs. The module isn't installed by default, and it isn't available for install as a Web Server (IIS) role service feature. The module must be downloaded from the IIS website. Use the Web Platform Installer to install the module:

1. Locally, navigate to the URL Rewrite Module downloads page. For the English version, select **WebPI** to download the WebPI installer. For other languages, select the appropriate architecture for the server (x86/x64) to download the installer.
2. Copy the installer to the server. Run the installer. Select the **Install** button and accept the license terms. A server restart isn't required after the install completes.

Configure the website

Set the website's **Physical path** to the app's folder. The folder contains:

- The `web.config` file that IIS uses to configure the website, including the required redirect rules and file content types.
- The app's static asset folder.

Host as an IIS sub-app

If a standalone app is hosted as an IIS sub-app, perform either of the following:

- Disable the inherited ASP.NET Core Module handler.

  Remove the handler in the Blazor app's published `web.config` file by adding a `<handlers>` section to the `<system.webServer>` section of the file:

  XML

  ```
  <handlers>
    <remove name="aspNetCore" />
  </handlers>
  ```

- Disable inheritance of the root (parent) app's `<system.webServer>` section using a `<location>` element with `inheritInChildApplications` set to `false`:

  XML

  ```
  <?xml version="1.0" encoding="utf-8"?>
  <configuration>
    <location path="." inheritInChildApplications="false">
      <system.webServer>
        <handlers>
          <add name="aspNetCore" ... />
        </handlers>
        <aspNetCore ... />
      </system.webServer>
    </location>
  </configuration>
  ```

> **Note**
>
> Disabling inheritance of the root (parent) app's `<system.webServer>` section is the default configuration for published apps using the .NET SDK.

Removing the handler or disabling inheritance is performed in addition to configuring the app's base path. Set the app base path in the app's `index.html` file to the IIS alias used when configuring the sub-app in IIS.

Configure the app's base path by following the guidance in the Host and deploy ASP.NET Core Blazor article.

Brotli and Gzip compression

This section only applies to standalone Blazor WebAssembly apps.

IIS can be configured via `web.config` to serve Brotli or Gzip compressed Blazor assets for standalone Blazor WebAssembly apps. For an example configuration file, see web.config.

Additional configuration of the example `web.config` file might be required in the following scenarios:

- The app's specification calls for either of the following:
  - Serving compressed files that aren't configured by the example `web.config` file.
  - Serving compressed files configured by the example `web.config` file in an uncompressed format.
- The server's IIS configuration (for example, `applicationHost.config`) provides server-level IIS defaults. Depending on the server-level configuration, the app might require a different IIS configuration than what the example `web.config` file contains.

For more information on custom `web.config` files, see the Use a custom web.config section.

Troubleshooting

If a *500 - Internal Server Error* is received and IIS Manager throws errors when attempting to access the website's configuration, confirm that the URL Rewrite Module is installed. When the module isn't installed, the `web.config` file can't be parsed by IIS.

This prevents the IIS Manager from loading the website's configuration and the website from serving Blazor's static files.

For more information on troubleshooting deployments to IIS, see Troubleshoot ASP.NET Core on Azure App Service and IIS.

Azure Storage

Azure Storage static file hosting allows serverless Blazor app hosting. Custom domain names, the Azure Content Delivery Network (CDN), and HTTPS are supported.

When the blob service is enabled for static website hosting on a storage account:

- Set the **Index document name** to `index.html`.
- Set the **Error document path** to `index.html`. Razor components and other non-file endpoints don't reside at physical paths in the static content stored by the blob service. When a request for one of these resources is received that the Blazor router should handle, the *404 - Not Found* error generated by the blob service routes the request to the **Error document path**. The `index.html` blob is returned, and the Blazor router loads and processes the path.

If files aren't loaded at runtime due to inappropriate MIME types in the files' `Content-Type` headers, take either of the following actions:

- Configure your tooling to set the correct MIME types (`Content-Type` headers) when the files are deployed.
- Change the MIME types (`Content-Type` headers) for the files after the app is deployed.

  In Storage Explorer (Azure portal) for each file:

  1. Right-click the file and select **Properties**.
  2. Set the **ContentType** and select the **Save** button.

For more information, see Static website hosting in Azure Storage.

Nginx

The following `nginx.conf` file is simplified to show how to configure Nginx to send the `index.html` file whenever it can't find a corresponding file on disk.

```
```

```
events { }
http {
    server {
        listen 80;

        location / {
            root      /usr/share/nginx/html;
            try_files $uri $uri/ /index.html =404;
        }
    }
}
```

When setting the NGINX burst rate limit with limit_req, Blazor WebAssembly apps may require a large `burst` parameter value to accommodate the relatively large number of requests made by an app. Initially, set the value to at least 60:

```
http {
    server {
        ...

        location / {
            ...

            limit_req zone=one burst=60 nodelay;
        }
    }
}
```

Increase the value if browser developer tools or a network traffic tool indicates that requests are receiving a *503 - Service Unavailable* status code.

For more information on production Nginx web server configuration, see Creating NGINX Plus and NGINX Configuration Files.

Apache

To deploy a Blazor WebAssembly app to Apache:

1. Create the Apache configuration file. The following example is a simplified configuration file (`blazorapp.config`):

   ```
   <VirtualHost *:80>
       ServerName www.example.com
   ```

```
    ServerAlias *.example.com

    DocumentRoot "/var/www/blazorapp"
    ErrorDocument 404 /index.html

    AddType application/wasm .wasm

    <Directory "/var/www/blazorapp">
        Options -Indexes
        AllowOverride None
    </Directory>

    <IfModule mod_deflate.c>
        AddOutputFilterByType DEFLATE text/css
        AddOutputFilterByType DEFLATE application/javascript
        AddOutputFilterByType DEFLATE text/html
        AddOutputFilterByType DEFLATE application/octet-stream
        AddOutputFilterByType DEFLATE application/wasm
        <IfModule mod_setenvif.c>
            BrowserMatch ^Mozilla/4 gzip-only-text/html
            BrowserMatch ^Mozilla/4.0[678] no-gzip
            BrowserMatch bMSIE !no-gzip !gzip-only-text/html
        </IfModule>
    </IfModule>

    ErrorLog /var/log/httpd/blazorapp-error.log
    CustomLog /var/log/httpd/blazorapp-access.log common
</VirtualHost>
```

1. Place the Apache configuration file into the `/etc/httpd/conf.d/` directory.
2. Place the app's published assets (`/bin/Release/{TARGET FRAMEWORK}/publish/wwwroot`, where the `{TARGET FRAMEWORK}` placeholder is the target framework) into the `/var/www/blazorapp` directory (the location specified to `DocumentRoot` in the configuration file).
3. Restart the Apache service.

For more information, see mod_mime and mod_deflate.

GitHub Pages

The default GitHub Action, which deploys pages, skips deployment of folders starting with underscore, for example, the `_framework` folder. To deploy folders starting with underscore, add an empty `.nojekyll` file to the Git branch.

Git treats JavaScript (JS) files, such as `blazor.webassembly.js`, as text and converts line endings from CRLF (carriage return-line feed) to LF (line feed) in the deployment

pipeline. These changes to JS files produce different file hashes than Blazor sends to the client in the `blazor.boot.json` file. The mismatches result in integrity check failures on the client. One approach to solving this problem is to add a `.gitattributes` file with `*.js binary` line before adding the app's assets to the Git branch. The `*.js binary` line configures Git to treat JS files as binary files, which avoids processing the files in the deployment pipeline. The file hashes of the unprocessed files match the entries in the `blazor.boot.json` file, and client-side integrity checks pass. For more information, see ASP.NET Core Blazor WebAssembly .NET runtime and app bundle caching.

To handle URL rewrites, add a `wwwroot/404.html` file with a script that handles redirecting the request to the `index.html` page. For an example, see the SteveSandersonMS/BlazorOnGitHubPages GitHub repository:

- wwwroot/404.html
- Live site

When using a project site instead of an organization site, update the `<base>` tag in `wwwroot/index.html`. Set the `href` attribute value to the GitHub repository name with a trailing slash (for example, `/my-repository/`). In the SteveSandersonMS/BlazorOnGitHubPages GitHub repository, the base `href` is updated at publish by the .github/workflows/main.yml configuration file.

> **Note**
>
> The SteveSandersonMS/BlazorOnGitHubPages GitHub repository isn't owned, maintained, or supported by the .NET Foundation or Microsoft.

Standalone with Docker

A standalone Blazor WebAssembly app is published as a set of static files for hosting by a static file server.

To host the app in Docker:

- Choose a Docker container with web server support, such as Ngnix or Apache.
- Copy the `publish` folder assets to a location folder defined in the web server for serving static files.
- Apply additional configuration as needed to serve the Blazor WebAssembly app.

For configuration guidance, see the following resources:

- Nginx section or Apache section of this article

- Docker Documentation

Host configuration values

Blazor WebAssembly apps can accept the following host configuration values as command-line arguments at runtime in the development environment.

Content root

The `--contentroot` argument sets the absolute path to the directory that contains the app's content files (content root). In the following examples, `/content-root-path` is the app's content root path.

- Pass the argument when running the app locally at a command prompt. From the app's directory, execute:

  .NET CLI

  ```
  dotnet watch --contentroot=/content-root-path
  ```

- Add an entry to the app's `launchSettings.json` file in the **IIS Express** profile. This setting is used when the app is run with the Visual Studio Debugger and from a command prompt with `dotnet watch` (or `dotnet run`).

  JSON

  ```
  "commandLineArgs": "--contentroot=/content-root-path"
  ```

- In Visual Studio, specify the argument in **Properties** > **Debug** > **Application arguments**. Setting the argument in the Visual Studio property page adds the argument to the `launchSettings.json` file.

  Console

  ```
  --contentroot=/content-root-path
  ```

Path base

The `--pathbase` argument sets the app base path for an app run locally with a non-root relative URL path (the `<base>` tag `href` is set to a path other than `/` for staging and

production). In the following examples, `/relative-URL-path` is the app's path base. For more information, see App base path.

> **ⓘ Important**
>
> Unlike the path provided to `href` of the `<base>` tag, don't include a trailing slash (`/`) when passing the `--pathbase` argument value. If the app base path is provided in the `<base>` tag as `<base href="/CoolApp/">` (includes a trailing slash), pass the command-line argument value as `--pathbase=/CoolApp` (no trailing slash).

- Pass the argument when running the app locally at a command prompt. From the app's directory, execute:

  .NET CLI

  ```
  dotnet watch --pathbase=/relative-URL-path
  ```

- Add an entry to the app's `launchSettings.json` file in the **IIS Express** profile. This setting is used when running the app with the Visual Studio Debugger and from a command prompt with `dotnet watch` (or `dotnet run`).

  JSON

  ```
  "commandLineArgs": "--pathbase=/relative-URL-path"
  ```

- In Visual Studio, specify the argument in **Properties** > **Debug** > **Application arguments**. Setting the argument in the Visual Studio property page adds the argument to the `launchSettings.json` file.

  Console

  ```
  --pathbase=/relative-URL-path
  ```

URLs

The `--urls` argument sets the IP addresses or host addresses with ports and protocols to listen on for requests.

- Pass the argument when running the app locally at a command prompt. From the app's directory, execute:

.NET CLI

```
dotnet watch --urls=http://127.0.0.1:0
```

- Add an entry to the app's `launchSettings.json` file in the **IIS Express** profile. This setting is used when running the app with the Visual Studio Debugger and from a command prompt with `dotnet watch` (or `dotnet run`).

JSON

```
"commandLineArgs": "--urls=http://127.0.0.1:0"
```

- In Visual Studio, specify the argument in **Properties** > **Debug** > **Application arguments**. Setting the argument in the Visual Studio property page adds the argument to the `launchSettings.json` file.

Console

```
--urls=http://127.0.0.1:0
```

Configure the Trimmer

Blazor performs Intermediate Language (IL) trimming on each Release build to remove unnecessary IL from the output assemblies. For more information, see Configure the Trimmer for ASP.NET Core Blazor.

Change the file name extension of DLL files

This section applies to ASP.NET Core 6.x and 7.x. In ASP.NET Core in .NET 8 or later, .NET assemblies are deployed as WebAssembly files (`.wasm`) using the Webcil file format. In ASP.NET Core in .NET 8 or later, this section only applies if the Webcil file format has been disabled in the app's project file.

If a firewall, anti-virus program, or network security appliance is blocking the transmission of the app's dynamic-link library (DLL) files (`.dll`), you can follow the guidance in this section to change the file name extensions of the app's published DLL files.

Note

Changing the file name extensions of the app's DLL files might not resolve the problem because many security systems scan the content of the app's files, not merely check file extensions.

For a more robust approach in environments that block the download and execution of DLL files, use ASP.NET Core in .NET 8 or later, which packages .NET assemblies as WebAssembly files (`.wasm`) using the Webcil file format. For more information, see the *Webcil packaging format for .NET assemblies* section in an 8.0 or later version of this article.

Third-party approaches exist for dealing with this problem. For more information, see the resources at Awesome Blazor.

After publishing the app, use a shell script or DevOps build pipeline to rename `.dll` files to use a different file extension in the directory of the app's published output.

In the following examples:

- PowerShell (PS) is used to update the file extensions.
- `.dll` files are renamed to use the `.bin` file extension from the command line.
- Files listed in the published `blazor.boot.json` file with a `.dll` file extension are updated to the `.bin` file extension.
- If service worker assets are also in use, a PowerShell command updates the `.dll` files listed in the `service-worker-assets.js` file to the `.bin` file extension.

To use a different file extension than `.bin`, replace `.bin` in the following commands with the desired file extension.

On Windows:

PowerShell

```
dir {PATH} | rename-item -NewName { $_.name -replace ".dll\b",".bin" }
((Get-Content {PATH}\blazor.boot.json -Raw) -replace '.dll"','.bin"') | Set-
Content {PATH}\blazor.boot.json
```

In the preceding command, the `{PATH}` placeholder is the path to the published `_framework` folder (for example, `.\bin\Release\net6.0\browser-wasm\publish\wwwroot\_framework` from the project's root folder).

If service worker assets are also in use:

PowerShell

```
((Get-Content {PATH}\service-worker-assets.js -Raw) -replace
'.dll"','.bin"') | Set-Content {PATH}\service-worker-assets.js
```

In the preceding command, the `{PATH}` placeholder is the path to the published `service-worker-assets.js` file.

On Linux or macOS:

Console

```
for f in {PATH}/*; do mv "$f" "`echo $f | sed -e 's/\.dll/.bin/g'`"; done
sed -i 's/\.dll"/.bin"/g' {PATH}/blazor.boot.json
```

In the preceding command, the `{PATH}` placeholder is the path to the published `_framework` folder (for example, `.\bin\Release\net6.0\browser-wasm\publish\wwwroot\_framework` from the project's root folder).

If service worker assets are also in use:

Console

```
sed -i 's/\.dll"/.bin"/g' {PATH}/service-worker-assets.js
```

In the preceding command, the `{PATH}` placeholder is the path to the published `service-worker-assets.js` file.

To address the compressed `blazor.boot.json.gz` and `blazor.boot.json.br` files, adopt either of the following approaches:

- Remove the compressed `blazor.boot.json.gz` and `blazor.boot.json.br` files. **Compression is disabled with this approach.**
- Recompress the updated `blazor.boot.json` file.

The preceding guidance for the compressed `blazor.boot.json` file also applies when service worker assets are in use. Remove or recompress `service-worker-assets.js.br` and `service-worker-assets.js.gz`. Otherwise, file integrity checks fail in the browser.

The following Windows example for .NET 6 uses a PowerShell script placed at the root of the project. The following script, which disables compression, is the basis for further modification if you wish to recompress the `blazor.boot.json` file.

`ChangeDLLExtensions.ps1:`:

PowerShell

```
param([string]$filepath,[string]$tfm)
dir $filepath\bin\Release\$tfm\browser-wasm\publish\wwwroot\_framework |
rename-item -NewName { $_.name -replace ".dll\b",".bin" }
((Get-Content $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\_framework\blazor.boot.json -Raw) -replace
'.dll"','.bin"') | Set-Content $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\_framework\blazor.boot.json
Remove-Item $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\_framework\blazor.boot.json.gz
Remove-Item $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\_framework\blazor.boot.json.br
```

If service worker assets are also in use, add the following commands:

PowerShell

```
((Get-Content $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\service-worker-assets.js -Raw) -replace
'.dll"','.bin"') | Set-Content $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\_framework\wwwroot\service-worker-assets.js
Remove-Item $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\_framework\wwwroot\service-worker-assets.js.gz
Remove-Item $filepath\bin\Release\$tfm\browser-
wasm\publish\wwwroot\_framework\wwwroot\service-worker-assets.js.br
```

In the project file, the script is executed after publishing the app for the `Release` configuration:

XML

```
<Target Name="ChangeDLLFileExtensions" AfterTargets="AfterPublish"
Condition="'$(Configuration)'=='Release'">
  <Exec Command="powershell.exe -command &amp;quot;&amp;amp; {
.\ChangeDLLExtensions.ps1 '$(SolutionDir)' '$(TargetFramework)'}&amp;quot;" />
</Target>
```

> **Note**
>
> When renaming and lazy loading the same assemblies, see the guidance in Lazy load assemblies in ASP.NET Core Blazor WebAssembly.

Usually, the app's server requires static asset configuration to serve the files with the updated extension. For an app hosted by IIS, add a MIME map entry (`<mimeMap>`) for the new file extension in the static content section (`<staticContent>`) in a custom

`web.config` file. The following example assumes that the file extension is changed from `.dll` to `.bin`:

XML

```
<staticContent>
  ...
  <mimeMap fileExtension=".bin" mimeType="application/octet-stream" />
  ...
</staticContent>
```

Include an update for compressed files if compression is in use:

```
<mimeMap fileExtension=".bin.br" mimeType="application/octet-stream" />
<mimeMap fileExtension=".bin.gz" mimeType="application/octet-stream" />
```

Remove the entry for the `.dll` file extension:

diff

```
- <mimeMap fileExtension=".dll" mimeType="application/octet-stream" />
```

Remove entries for compressed `.dll` files if compression is in use:

diff

```
- <mimeMap fileExtension=".dll.br" mimeType="application/octet-stream" />
- <mimeMap fileExtension=".dll.gz" mimeType="application/octet-stream" />
```

For more information on custom `web.config` files, see the Use a custom web.config section.

Prior deployment corruption

Typically on deployment:

- Only the files that have changed are replaced, which usually results in a faster deployment.
- Existing files that aren't part of the new deployment are left in place for use by the new deployment.

In rare cases, lingering files from a prior deployment can corrupt a new deployment. Completely deleting the existing deployment (or locally-published app prior to deployment) may resolve the issue with a corrupted deployment. Often, deleting the existing deployment ***once*** is sufficient to resolve the problem, including for a DevOps build and deploy pipeline.

If you determine that clearing a prior deployment is always required when a DevOps build and deploy pipeline is in use, you can temporarily add a step to the build pipeline to delete the prior deployment for each new deployment until you troubleshoot the exact cause of the corruption.

Resolve integrity check failures

When Blazor WebAssembly downloads an app's startup files, it instructs the browser to perform integrity checks on the responses. Blazor sends SHA-256 hash values for DLL (`.dll`), WebAssembly (`.wasm`), and other files in the `blazor.boot.json` file, which isn't cached on clients. The file hashes of cached files are compared to the hashes in the `blazor.boot.json` file. For cached files with a matching hash, Blazor uses the cached files. Otherwise, files are requested from the server. After a file is downloaded, its hash is checked again for integrity validation. An error is generated by the browser if any downloaded file's integrity check fails.

Blazor's algorithm for managing file integrity:

- Ensures that the app doesn't risk loading an inconsistent set of files, for example if a new deployment is applied to your web server while the user is in the process of downloading the application files. Inconsistent files can result in a malfunctioning app.
- Ensures the user's browser never caches inconsistent or invalid responses, which can prevent the app from starting even if the user manually refreshes the page.
- Makes it safe to cache the responses and not check for server-side changes until the expected SHA-256 hashes themselves change, so subsequent page loads involve fewer requests and complete faster.

If the web server returns responses that don't match the expected SHA-256 hashes, an error similar to the following example appears in the browser's developer console:

> Failed to find a valid digest in the 'integrity' attribute for resource 'https://myapp.example.com/_framework/MyBlazorApp.dll' with computed SHA-256 integrity 'IIa70iwvmEg5WiDV17OpQ5eCztNYqL186J56852RpJY='. The resource has been blocked.

In most cases, the warning doesn't indicate a problem with integrity checking. Instead, the warning usually means that some other problem exists.

For Blazor WebAssembly's boot reference source, see the Boot.WebAssembly.ts file in the dotnet/aspnetcore GitHub repository.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Diagnosing integrity problems

When an app is built, the generated `blazor.boot.json` manifest describes the SHA-256 hashes of boot resources at the time that the build output is produced. The integrity check passes as long as the SHA-256 hashes in `blazor.boot.json` match the files delivered to the browser.

Common reasons why this fails include:

- The web server's response is an error (for example, a *404 - Not Found* or a *500 - Internal Server Error*) instead of the file the browser requested. This is reported by the browser as an integrity check failure and not as a response failure.
- Something has changed the contents of the files between the build and delivery of the files to the browser. This might happen:
  - If you or build tools manually modify the build output.
  - If some aspect of the deployment process modified the files. For example if you use a Git-based deployment mechanism, bear in mind that Git transparently converts Windows-style line endings to Unix-style line endings if you commit files on Windows and check them out on Linux. Changing file line endings change the SHA-256 hashes. To avoid this problem, consider using .gitattributes to treat build artifacts as binary files.
  - The web server modifies the file contents as part of serving them. For example, some content distribution networks (CDNs) automatically attempt to minify HTML, thereby modifying it. You may need to disable such features.
- The `blazor.boot.json` file fails to load properly or is improperly cached on the client. Common causes include either of the following:
  - Misconfigured or malfunctioning custom developer code.

    - One or more misconfigured intermediate caching layers.

To diagnose which of these applies in your case:

1. Note which file is triggering the error by reading the error message.
2. Open your browser's developer tools and look in the *Network* tab. If necessary, reload the page to see the list of requests and responses. Find the file that is triggering the error in that list.
3. Check the HTTP status code in the response. If the server returns anything other than *200 - OK* (or another 2xx status code), then you have a server-side problem to diagnose. For example, status code 403 means there's an authorization problem, whereas status code 500 means the server is failing in an unspecified manner. Consult server-side logs to diagnose and fix the app.
4. If the status code is *200 - OK* for the resource, look at the response content in browser's developer tools and check that the content matches up with the data expected. For example, a common problem is to misconfigure routing so that requests return your `index.html` data even for other files. Make sure that responses to `.wasm` requests are WebAssembly binaries and that responses to `.dll` requests are .NET assembly binaries. If not, you have a server-side routing problem to diagnose.
5. Seek to validate the app's published and deployed output with the Troubleshoot integrity PowerShell script.

If you confirm that the server is returning plausibly correct data, there must be something else modifying the contents in between build and delivery of the file. To investigate this:

- Examine the build toolchain and deployment mechanism in case they're modifying files after the files are built. An example of this is when Git transforms file line endings, as described earlier.
- Examine the web server or CDN configuration in case they're set up to modify responses dynamically (for example, trying to minify HTML). It's fine for the web server to implement HTTP compression (for example, returning `content-encoding: br` or `content-encoding: gzip`), since this doesn't affect the result after decompression. However, it's *not* fine for the web server to modify the uncompressed data.

Troubleshoot integrity PowerShell script

Use the integrity.ps1 PowerShell script to validate a published and deployed Blazor app. The script is provided for PowerShell Core 7 or later as a starting point when the app has integrity issues that the Blazor framework can't identify. Customization of the

script might be required for your apps, including if running on version of PowerShell later than version 7.2.0.

The script checks the files in the `publish` folder and downloaded from the deployed app to detect issues in the different manifests that contain integrity hashes. These checks should detect the most common problems:

- You modified a file in the published output without realizing it.
- The app wasn't correctly deployed to the deployment target, or something changed within the deployment target's environment.
- There are differences between the deployed app and the output from publishing the app.

Invoke the script with the following command in a PowerShell command shell:

PowerShell

```
.\integrity.ps1 {BASE URL} {PUBLISH OUTPUT FOLDER}
```

In the following example, the script is executed on a locally-running app at `https://localhost:5001/`:

PowerShell

```
.\integrity.ps1 https://localhost:5001/
C:\TestApps\BlazorSample\bin\Release\net6.0\publish\
```

Placeholders:

- `{BASE URL}`: The URL of the deployed app. A trailing slash (`/`) is required.
- `{PUBLISH OUTPUT FOLDER}`: The path to the app's `publish` folder or location where the app is published for deployment.

> **Note**
>
> When cloning the `dotnet/AspNetCore.Docs` GitHub repository, the `integrity.ps1` script might be quarantined by Bitdefender or another virus scanner present on the system. Usually, the file is trapped by a virus scanner's *heuristic scanning* technology, which merely looks for patterns in files that might indicate the presence of malware. To prevent the virus scanner from quarantining the file, add an exception to the virus scanner prior to cloning the repo. The following example is a typical path to the script on a Windows system. Adjust the path as needed for other systems. The `{USER}` placeholder is the user's path segment.

```
C:\Users\
{USER}\Documents\GitHub\AspNetCore.Docs\aspnetcore\blazor\host-and-
deploy\webassembly\_samples\integrity.ps1
```

Warning: *Creating virus scanner exceptions is dangerous and should only be performed when you're certain that the file is safe.*

Comparing the checksum of a file to a valid checksum value doesn't guarantee file safety, but modifying a file in a way that maintains a checksum value isn't trivial for malicious users. Therefore, checksums are useful as a general security approach. Compare the checksum of the local `integrity.ps1` file to one of the following values:

- SHA256: `32c24cb667d79a701135cb72f6bae490d81703323f61b8af2c7e5e5dc0f0c2bb`
- MD5: `9cee7d7ec86ee809a329b5406fbf21a8`

Obtain the file's checksum on Windows OS with the following command. Provide the path and file name for the `{PATH AND FILE NAME}` placeholder and indicate the type of checksum to produce for the `{SHA512|MD5}` placeholder, either `SHA256` or `MD5`:

Console

```
CertUtil -hashfile {PATH AND FILE NAME} {SHA256|MD5}
```

If you have any cause for concern that checksum validation isn't secure enough in your environment, consult your organization's security leadership for guidance.

For more information, see Overview of threat protection by Microsoft Defender Antivirus.

Disable integrity checking for non-PWA apps

In most cases, don't disable integrity checking. Disabling integrity checking doesn't solve the underlying problem that has caused the unexpected responses and results in losing the benefits listed earlier.

There may be cases where the web server can't be relied upon to return consistent responses, and you have no choice but to temporarily disable integrity checks until the underlying problem is resolved.

To disable integrity checks, add the following to a property group in the Blazor WebAssembly app's project file (`.csproj`):

```xml
<BlazorCacheBootResources>false</BlazorCacheBootResources>
```

`BlazorCacheBootResources` also disables Blazor's default behavior of caching the `.dll`, `.wasm`, and other files based on their SHA-256 hashes because the property indicates that the SHA-256 hashes can't be relied upon for correctness. Even with this setting, the browser's normal HTTP cache may still cache those files, but whether or not this happens depends on your web server configuration and the `cache-control` headers that it serves.

> **Note**
>
> The `BlazorCacheBootResources` property doesn't disable integrity checks for Progressive Web Applications (PWAs). For guidance pertaining to PWAs, see the Disable integrity checking for PWAs section.

We can't provide an exhaustive list of scenarios where disabling integrity checking is required. Servers can answer a request in arbitrary ways outside of the scope of the Blazor framework. The framework provides the `BlazorCacheBootResources` setting to make the app runnable at the cost of *losing a guarantee of integrity that the app can provide*. Again, we don't recommend disabling integrity checking, especially for production deployments. Developers should seek to solve the underlying integrity problem that's causing integrity checking to fail.

A few general cases that can cause integrity issues are:

- Running on HTTP where integrity can't be checked.
- If your deployment process modifies the files after publish in any way.
- If your host modifies the files in any way.

Disable integrity checking for PWAs

Blazor's Progressive Web Application (PWA) template contains a suggested `service-worker.published.js` file that's responsible for fetching and storing application files for offline use. This is a separate process from the normal app startup mechanism and has its own separate integrity checking logic.

Inside the `service-worker.published.js` file, following line is present:

```JavaScript
.map(asset => new Request(asset.url, { integrity: asset.hash }));
```

To disable integrity checking, remove the `integrity` parameter by changing the line to the following:

```JavaScript
.map(asset => new Request(asset.url));
```

Again, disabling integrity checking means that you lose the safety guarantees offered by integrity checking. For example, there is a risk that if the user's browser is caching the app at the exact moment that you deploy a new version, it could cache some files from the old deployment and some from the new deployment. If that happens, the app becomes stuck in a broken state until you deploy a further update.

ASP.NET Core Blazor WebAssembly .NET runtime and app bundle caching

Article • 07/09/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

When a Blazor WebAssembly app loads in the browser, the app downloads boot resources from the server:

- JavaScript code to bootstrap the app
- .NET runtime and assemblies
- Locale specific data

Except for Blazor's boot resources file (`blazor.boot.json`), WebAssembly .NET runtime and app bundle files are cached on clients. The `blazor.boot.json` file contains a manifest of the files that make up the app that must be downloaded along with a hash of the file's content that's used to detect whether any of the boot resources have changed. Blazor caches downloaded files using the browser Cache API.

When Blazor WebAssembly downloads an app's startup files, it instructs the browser to perform integrity checks on the responses. Blazor sends SHA-256 hash values for DLL (`.dll`), WebAssembly (`.wasm`), and other files in the `blazor.boot.json` file. The file hashes of cached files are compared to the hashes in the `blazor.boot.json` file. For cached files with a matching hash, Blazor uses the cached files. Otherwise, files are requested from the server. After a file is downloaded, its hash is checked again for integrity validation. An error is generated by the browser if any downloaded file's integrity check fails.

Blazor's algorithm for managing file integrity:

- Ensures that the app doesn't risk loading an inconsistent set of files, for example if a new deployment is applied to your web server while the user is in the process of downloading the application files. Inconsistent files can result in a malfunctioning app.

- Ensures the user's browser never caches inconsistent or invalid responses, which can prevent the app from starting even if the user manually refreshes the page.
- Makes it safe to cache the responses and not check for server-side changes until the expected SHA-256 hashes themselves change, so subsequent page loads involve fewer requests and complete faster.

If the web server returns responses that don't match the expected SHA-256 hashes, an error similar to the following example appears in the browser's developer console:

> Failed to find a valid digest in the 'integrity' attribute for resource 'https://myapp.example.com/_framework/MyBlazorApp.dll' with computed SHA-256 integrity 'Ila70iwvmEg5WiDV17OpQ5eCztNYqL186J56852RpJY='. The resource has been blocked.

In most cases, the warning doesn't indicate a problem with integrity checking. Instead, the warning usually means that some other problem exists.

> ⓘ **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

Diagnosing integrity problems

When an app is built, the generated `blazor.boot.json` manifest describes the SHA-256 hashes of boot resources at the time that the build output is produced. The integrity check passes as long as the SHA-256 hashes in `blazor.boot.json` match the files delivered to the browser.

Common reasons why this fails include:

- The web server's response is an error (for example, a *404 - Not Found* or a *500 - Internal Server Error*) instead of the file the browser requested. This is reported by the browser as an integrity check failure and not as a response failure.
- Something has changed the contents of the files between the build and delivery of the files to the browser. This might happen:
  - If you or build tools manually modify the build output.

    - If some aspect of the deployment process modified the files. For example if you use a Git-based deployment mechanism, bear in mind that Git transparently converts Windows-style line endings to Unix-style line endings if you commit files on Windows and check them out on Linux. Changing file line endings change the SHA-256 hashes. To avoid this problem, consider using .gitattributes to treat build artifacts as binary files.
    - The web server modifies the file contents as part of serving them. For example, some content distribution networks (CDNs) automatically attempt to minify HTML, thereby modifying it. You may need to disable such features.
- The `blazor.boot.json` file fails to load properly or is improperly cached on the client. Common causes include either of the following:
    - Misconfigured or malfunctioning custom developer code.
    - One or more misconfigured intermediate caching layers.

To diagnose which of these applies in your case:

1. Note which file is triggering the error by reading the error message.
2. Open your browser's developer tools and look in the *Network* tab. If necessary, reload the page to see the list of requests and responses. Find the file that is triggering the error in that list.
3. Check the HTTP status code in the response. If the server returns anything other than *200 - OK* (or another 2xx status code), then you have a server-side problem to diagnose. For example, status code 403 means there's an authorization problem, whereas status code 500 means the server is failing in an unspecified manner. Consult server-side logs to diagnose and fix the app.
4. If the status code is *200 - OK* for the resource, look at the response content in browser's developer tools and check that the content matches up with the data expected. For example, a common problem is to misconfigure routing so that requests return your `index.html` data even for other files. Make sure that responses to `.wasm` requests are WebAssembly binaries and that responses to `.dll` requests are .NET assembly binaries. If not, you have a server-side routing problem to diagnose.
5. Seek to validate the app's published and deployed output with the Troubleshoot integrity PowerShell script.

If you confirm that the server is returning plausibly correct data, there must be something else modifying the contents in between build and delivery of the file. To investigate this:

- Examine the build toolchain and deployment mechanism in case they're modifying files after the files are built. An example of this is when Git transforms file line endings, as described earlier.

- Examine the web server or CDN configuration in case they're set up to modify responses dynamically (for example, trying to minify HTML). It's fine for the web server to implement HTTP compression (for example, returning `content-encoding: br` or `content-encoding: gzip`), since this doesn't affect the result after decompression. However, it's *not* fine for the web server to modify the uncompressed data.

Troubleshoot integrity PowerShell script

Use the integrity.ps1 PowerShell script to validate a published and deployed Blazor app. The script is provided for PowerShell Core 7 or later as a starting point when the app has integrity issues that the Blazor framework can't identify. Customization of the script might be required for your apps, including if running on version of PowerShell later than version 7.2.0.

The script checks the files in the `publish` folder and downloaded from the deployed app to detect issues in the different manifests that contain integrity hashes. These checks should detect the most common problems:

- You modified a file in the published output without realizing it.
- The app wasn't correctly deployed to the deployment target, or something changed within the deployment target's environment.
- There are differences between the deployed app and the output from publishing the app.

Invoke the script with the following command in a PowerShell command shell:

PowerShell

```
.\integrity.ps1 {BASE URL} {PUBLISH OUTPUT FOLDER}
```

In the following example, the script is executed on a locally-running app at `https://localhost:5001/`:

PowerShell

```
.\integrity.ps1 https://localhost:5001/
C:\TestApps\BlazorSample\bin\Release\net6.0\publish\
```

Placeholders:

- `{BASE URL}`: The URL of the deployed app. A trailing slash (`/`) is required.

- `{PUBLISH OUTPUT FOLDER}`: The path to the app's `publish` folder or location where the app is published for deployment.

> **Note**
>
> When cloning the `dotnet/AspNetCore.Docs` GitHub repository, the `integrity.ps1` script might be quarantined by **Bitdefender** or another virus scanner present on the system. Usually, the file is trapped by a virus scanner's *heuristic scanning* technology, which merely looks for patterns in files that might indicate the presence of malware. To prevent the virus scanner from quarantining the file, add an exception to the virus scanner prior to cloning the repo. The following example is a typical path to the script on a Windows system. Adjust the path as needed for other systems. The `{USER}` placeholder is the user's path segment.
>
> ```
> C:\Users\
> {USER}\Documents\GitHub\AspNetCore.Docs\aspnetcore\blazor\host-and-
> deploy\webassembly_samples\integrity.ps1
> ```
>
> **Warning**: *Creating virus scanner exceptions is dangerous and should only be performed when you're certain that the file is safe.*
>
> Comparing the checksum of a file to a valid checksum value doesn't guarantee file safety, but modifying a file in a way that maintains a checksum value isn't trivial for malicious users. Therefore, checksums are useful as a general security approach. Compare the checksum of the local `integrity.ps1` file to one of the following values:
>
> - SHA256: `32c24cb667d79a701135cb72f6bae490d81703323f61b8af2c7e5e5dc0f0c2bb`
> - MD5: `9cee7d7ec86ee809a329b5406fbf21a8`
>
> Obtain the file's checksum on Windows OS with the following command. Provide the path and file name for the `{PATH AND FILE NAME}` placeholder and indicate the type of checksum to produce for the `{SHA512|MD5}` placeholder, either `SHA256` or `MD5`:
>
> Console
>
> ```
> CertUtil -hashfile {PATH AND FILE NAME} {SHA256|MD5}
> ```

If you have any cause for concern that checksum validation isn't secure enough in your environment, consult your organization's security leadership for guidance.

For more information, see Overview of threat protection by Microsoft Defender Antivirus.

Disable resource caching and integrity checks for non-PWA apps

In most cases, don't disable integrity checking. Disabling integrity checking doesn't solve the underlying problem that has caused the unexpected responses and results in losing the benefits listed earlier.

There may be cases where the web server can't be relied upon to return consistent responses, and you have no choice but to temporarily disable integrity checks until the underlying problem is resolved.

To disable integrity checks, add the following to a property group in the Blazor WebAssembly app's project file (`.csproj`):

```xml
<BlazorCacheBootResources>false</BlazorCacheBootResources>
```

`BlazorCacheBootResources` also disables Blazor's default behavior of caching the `.dll`, `.wasm`, and other files based on their SHA-256 hashes because the property indicates that the SHA-256 hashes can't be relied upon for correctness. Even with this setting, the browser's normal HTTP cache may still cache those files, but whether or not this happens depends on your web server configuration and the `cache-control` headers that it serves.

> **Note**
>
> The `BlazorCacheBootResources` property doesn't disable integrity checks for Progressive Web Applications (PWAs). For guidance pertaining to PWAs, see the Disable integrity checking for PWAs section.

We can't provide an exhaustive list of scenarios where disabling integrity checking is required. Servers can answer a request in arbitrary ways outside of the scope of the Blazor framework. The framework provides the `BlazorCacheBootResources` setting to

make the app runnable at the cost of *losing a guarantee of integrity that the app can provide*. Again, we don't recommend disabling integrity checking, especially for production deployments. Developers should seek to solve the underlying integrity problem that's causing integrity checking to fail.

A few general cases that can cause integrity issues are:

- Running on HTTP where integrity can't be checked.
- If your deployment process modifies the files after publish in any way.
- If your host modifies the files in any way.

Disable resource caching and integrity checks for PWAs

Blazor's Progressive Web Application (PWA) template contains a suggested `service-worker.published.js` file that's responsible for fetching and storing application files for offline use. This is a separate process from the normal app startup mechanism and has its own separate integrity checking logic.

Inside the `service-worker.published.js` file, following line is present:

```
JavaScript

.map(asset => new Request(asset.url, { integrity: asset.hash }));
```

To disable integrity checking, remove the `integrity` parameter by changing the line to the following:

```
JavaScript

.map(asset => new Request(asset.url));
```

Again, disabling integrity checking means that you lose the safety guarantees offered by integrity checking. For example, there is a risk that if the user's browser is caching the app at the exact moment that you deploy a new version, it could cache some files from the old deployment and some from the new deployment. If that happens, the app becomes stuck in a broken state until you deploy a further update.

Avoid HTTP caching issues when upgrading ASP.NET Core Blazor apps

Article • 04/05/2024

When Blazor apps are incorrectly upgraded or configured, it can result in non-seamless upgrades for existing users. This article discusses some of the common HTTP caching issues that can occur when upgrading Blazor apps across major versions. It also provides some recommended actions to ensure a smooth transition for your users.

While future Blazor releases might provide better solutions for dealing with HTTP caching issues, it's ultimately up to the app to correctly configure caching. Proper caching configuration ensures that the app's users always have the most up-to-date version of the app, improving their experience and reducing the likelihood of encountering errors.

Common problems that negatively impact the user upgrade experience include:

- **Incorrect handling of project and package updates**: This happens if you don't update all of the app's deployed projects to use the same major framework version or if you use packages from a previous version when a newer version is available as part of the major upgrade.
- **Incorrect configuration of caching headers**: HTTP caching headers control how, where, and for how long the app's responses are cached. If headers aren't configured correctly, users might receive stale content.
- **Incorrect configuration of other layers**: Content Delivery Networks (CDNs) and other layers of the deployed app can cause issues if incorrectly configured. For example, CDNs are designed to cache and deliver content to improve performance and reduce latency. If a CDN is incorrectly serving cached versions of assets, it can lead to stale content delivery to the user.

Detect and diagnose upgrade issues

Upgrade issues typically appear as a failure to start the app in the browser. Normally, a warning indicates the presence of a stale asset or an asset that's missing or inconsistent with the app.

- First, check if the app loads successfully within a clean browser instance. Use a private browser mode to load the app, such as Microsoft Edge InPrivate mode or Google Chrome Incognito mode. If the app fails to load, it likely means that one or more packages or the framework wasn't correctly updated.

- If the app loads correctly in a clean browser instance, then it's likely that the app is being served from a stale cache. In most cases, a hard browser refresh with `Ctrl`+`F5` flushes the cache, which permits the app to load and run with the latest assets.
- If the app continues to fail, then it's likely that a stale CDN cache is serving the app. Try to flush the DNS cache via whatever mechanism your CDN provider offers.

Recommended actions before an upgrade

The prior process for serving the app might make the update process more challenging. For example, avoiding or incorrectly using caching headers in the past can lead to current caching problems for users. You can take the actions in the following sections to mitigate the issue and improve the upgrade process for users.

Align framework packages with the framework version

Ensure that framework packages line up with the framework version. Using packages from a previous version when a newer version is available can lead to compatibility issues. It's also important to ensure that all of the app's deployed projects use the same major framework version. This consistency helps to avoid unexpected behavior and errors.

Verify the presence of correct caching headers

The correct caching headers should be present on responses to resource requests. This includes `ETag`, `Cache-Control`, and other caching headers. The configuration of these headers is dependent on the hosting service or hosting server platform. They are particularly important for assets such as the Blazor script (`blazor.webassembly.js`) and anything the script downloads.

Incorrect HTTP caching headers may also impact service workers. Service workers rely on caching headers to manage cached resources effectively. Therefore, incorrect or missing headers can disrupt the service worker's functionality.

Use `Clear-Site-Data` to delete state in the browser

Consider using the Clear-Site-Data header to delete state in the browser.

Usually the source of cache state problems is limited to the HTTP browser cache, so use of the `cache` directive should be sufficient. This action can help to ensure that the

browser fetches the latest resources from the server, rather than serving stale content from the cache.

You can optionally include the `storage` directive to clear local storage caches at the same time that you're clearing the HTTP browser cache. However, apps that use client storage might experience a loss of important information if the `storage` directive is used.

Append a query string to the Blazor script tag

If none of the previous recommended actions are effective, possible to use for your deployment, or apply to your app, consider temporarily appending a query string to the Blazor script's `<script>` tag source. This action should be enough in most situations to force the browser to bypass the local HTTP cache and download a new version of the app. There's no need to read or use the query string in the app.

In the following example, the query string `temporaryQueryString=1` is temporarily applied to the `<script>` tag's relative external source URI:

HTML

```
<script src="_framework/blazor.webassembly.js?temporaryQueryString=1">
</script>
```

After all of the app's users have reloaded the app, the query string can be removed.

Alternatively, you can apply a persistent query string with relevant versioning. The following example assumes that the version of the app matches the .NET release version (`8` for .NET 8):

HTML

```
<script src="_framework/blazor.webassembly.js?version=8"></script>
```

For the location of the Blazor script `<script>` tag, see ASP.NET Core Blazor project structure.

Configure the Trimmer for ASP.NET Core Blazor

Article • 09/12/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article explains how to control the Intermediate Language (IL) Trimmer when building a Blazor app.

Blazor WebAssembly performs Intermediate Language (IL) trimming to reduce the size of the published output. Trimming occurs when publishing an app.

Trimming may have detrimental effects for the published app. In apps that use reflection, the IL Trimmer often can't determine the required types for runtime reflection and trim them away. For example, complex framework types for JS interop, such as KeyValuePair, might be trimmed and not available at runtime for JS interop calls. In these cases, we recommend creating your own custom types instead. The IL Trimmer is also unable to react to an app's dynamic behavior at runtime. To ensure the trimmed app works correctly once deployed, test published output frequently while developing.

Configuration

To configure the IL Trimmer, see the Trimming options article in the .NET Fundamentals documentation, which includes guidance on the following subjects:

- Disable trimming for the entire app with the `<PublishTrimmed>` property in the project file.
- Control how aggressively unused IL is discarded by the IL Trimmer.
- Stop the IL Trimmer from trimming specific assemblies.
- "Root" assemblies for trimming.
- Surface warnings for reflected types by setting the `<SuppressTrimAnalysisWarnings>` property to `false` in the project file.
- Control symbol trimming and debugger support.

- Set IL Trimmer features for trimming framework library features.

Default trimmer granularity

The default trimmer granularity for Blazor apps is `partial`. To trim all assemblies, change the granularity to `full` in the app's project file:

XML

```xml
<ItemGroup>
  <TrimMode>full</TrimMode>
</ItemGroup>
```

For more information, see Trimming options (.NET documentation).

Deployment layout for ASP.NET Core hosted Blazor WebAssembly apps

Article • 09/12/2024

This article explains how to enable hosted Blazor WebAssembly deployments in environments that block the download and execution of dynamic-link library (DLL) files.

> **Note**
>
> This guidance addresses environments that block clients from downloading and executing DLLs. In .NET 8 or later, Blazor uses the Webcil file format to address this problem. For more information, see Host and deploy ASP.NET Core Blazor WebAssembly. Multipart bundling using the experimental NuGet package described by this article isn't supported for Blazor apps in .NET 8 or later. You can use the guidance in this article to create your own multipart bundling NuGet package for .NET 8 or later.

Blazor WebAssembly apps require dynamic-link libraries (DLLs) to function, but some environments block clients from downloading and executing DLLs. In a subset of these environments, changing the file name extension of DLL files (.dll) is sufficient to bypass security restrictions, but security products are often able to scan the content of files traversing the network and block or quarantine DLL files. This article describes one approach for enabling Blazor WebAssembly apps in these environments, where a multipart bundle file is created from the app's DLLs so that the DLLs can be downloaded together bypassing security restrictions.

A hosted Blazor WebAssembly app can customize its published files and packaging of app DLLs using the following features:

- JavaScript initializers that allow customizing the Blazor boot process.
- MSBuild extensibility to transform the list of published files and define *Blazor Publish Extensions*. Blazor Publish Extensions are files defined during the publish process that provide an alternative representation for the set of files required to run a published Blazor WebAssembly app. In this article, a Blazor Publish Extension is created that produces a multipart bundle with all of the app's DLLs packed into a single file so that the DLLs can be downloaded together.

The approach demonstrated in this article serves as a starting point for developers to devise their own strategies and custom loading processes.

> ⚠ **Warning**
>
> Any approach taken to circumvent a security restriction must be carefully considered for its security implications. We recommend exploring the subject further with your organization's network security professionals before adopting the approach in this article. Alternatives to consider include:
>
> - Enable security appliances and security software to permit network clients to download and use the exact files required by a Blazor WebAssembly app.
> - Switch from the Blazor WebAssembly hosting model to the **Blazor Server hosting model**, which maintains all of the app's C# code on the server and doesn't require downloading DLLs to clients. Blazor Server also offers the advantage of keeping C# code private without requiring the use of web API apps for C# code privacy with Blazor WebAssembly apps.

Experimental NuGet package and sample app

The approach described in this article is used by the *experimental* Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle package (NuGet.org) for apps targeting .NET 6 or later. The package contains MSBuild targets to customize the Blazor publish output and a JavaScript initializer to use a custom boot resource loader, each of which are described in detail later in this article.

Experimental code (includes the NuGet package reference source and CustomPackagedApp sample app)

> ⚠ **Warning**
>
> Experimental and preview features are provided for the purpose of collecting feedback and aren't supported for production use.

Later in this article, the Customize the Blazor WebAssembly loading process via a NuGet package section with its three subsections provide detailed explanations on the configuration and code in the `Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle` package. The detailed explanations are important to understand when you create your own strategy and custom loading process for Blazor WebAssembly apps. To use the published, experimental, unsupported NuGet package without customization as a **local demonstration**, perform the following steps:

1. Use an existing hosted Blazor WebAssembly solution or create a new solution from the Blazor WebAssembly project template using Visual Studio or by passing the -ho|--hosted option to the dotnet new command (`dotnet new blazorwasm -ho`). For more information, see Tooling for ASP.NET Core Blazor.

2. In the **Client** project, add the experimental `Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle` package.

   > ⓘ **Note**
   >
   > For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

3. In the **Server** project, add an endpoint for serving the bundle file (`app.bundle`). Example code can be found in the Serve the bundle from the host server app section of this article.

4. Publish the app in Release configuration.

Customize the Blazor WebAssembly loading process via a NuGet package

> ⚠ **Warning**
>
> The guidance in this section with its three subsections pertains to building a NuGet package from scratch to implement your own strategy and custom loading process. The *experimental* Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle package (NuGet.org) for .NET 6 and 7 is based on the guidance in this section. When using the provided package in a **local demonstration** of the multipart bundle download approach, you don't need to follow the guidance in this section. For guidance on how to use the provided package, see the Experimental NuGet package and sample app section.

Blazor app resources are packed into a multipart bundle file and loaded by the browser via a custom JavaScript (JS) initializer. For an app consuming the package with the JS initializer, the app only requires that the bundle file is served when requested. All of the other aspects of this approach are handled transparently.

Four customizations are required to how a default published Blazor app loads:

- An MSBuild task to transform the publish files.
- A NuGet package with MSBuild targets that hooks into the Blazor publishing process, transforms the output, and defines one or more Blazor Publish Extension files (in this case, a single bundle).
- A JS initializer to update the Blazor WebAssembly resource loader callback so that it loads the bundle and provides the app with the individual files.
- A helper on the host **Server** app to ensure that the bundle is served to clients on request.

Create an MSBuild task to customize the list of published files and define new extensions

Create an MSBuild task as a public C# class that can be imported as part of an MSBuild compilation and that can interact with the build.

The following are required for the C# class:

- A new class library project.
- A project target framework of `netstandard2.0`.
- References to MSBuild packages:
  - Microsoft.Build.Framework
  - Microsoft.Build.Utilities.Core

> **Note**
>
> The NuGet package for the examples in this article are named after the package provided by Microsoft, `Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle`. For guidance on naming and producing your own NuGet package, see the following NuGet articles:
>
> - Package authoring best practices
> - Package ID prefix reservation

`Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tasks/Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tasks.csproj`:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk">
```

```
  <PropertyGroup>
    <TargetFramework>netstandard2.0</TargetFramework>
    <LangVersion>8.0</LangVersion>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.Build.Framework" Version="
{VERSION}" />
    <PackageReference Include="Microsoft.Build.Utilities.Core" Version="
{VERSION}" />
  </ItemGroup>

</Project>
```

Determine the latest package versions for the `{VERSION}` placeholders at NuGet.org:

- Microsoft.Build.Framework
- Microsoft.Build.Utilities.Core

To create the MSBuild task, create a public C# class extending Microsoft.Build.Utilities.Task (not System.Threading.Tasks.Task) and declare three properties:

- `PublishBlazorBootStaticWebAsset`: The list of files to publish for the Blazor app.
- `BundlePath`: The path where the bundle is written.
- `Extension`: The new Publish Extensions to include in the build.

The following example `BundleBlazorAssets` class is a starting point for further customization:

- In the `Execute` method, the bundle is created from the following three file types:
  - JavaScript files (`dotnet.js`)
  - WASM files (`dotnet.wasm`)
  - App DLLs (`.dll`)
- A `multipart/form-data` bundle is created. Each file is added to the bundle with its respective descriptions via the Content-Disposition header and the Content-Type header.
- After the bundle is created, the bundle is written to a file.
- The build is configured for the extension. The following code creates an extension item and adds it to the `Extension` property. Each extension item contains three pieces of data:
  - The path to the extension file.
  - The URL path relative to the root of the Blazor WebAssembly app.
  - The name of the extension, which groups the files produced by a given extension.

After accomplishing the preceding goals, the MSBuild task is created for customizing the Blazor publish output. Blazor takes care of gathering the extensions and making sure that the extensions are copied to the correct location in the publish output folder (for example, `bin\Release\net6.0\publish`). The same optimizations (for example, compression) are applied to the JavaScript, WASM, and DLL files as Blazor applies to other files.

`Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tasks/BundleBlazorAssets.cs`:

C#

```
using System.IO;
using System.Net.Http;
using System.Net.Http.Headers;
using Microsoft.Build.Framework;
using Microsoft.Build.Utilities;

namespace Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tasks
{
    public class BundleBlazorAssets : Task
    {
        [Required]
        public ITaskItem[]? PublishBlazorBootStaticWebAsset { get; set; }

        [Required]
        public string? BundlePath { get; set; }

        [Output]
        public ITaskItem[]? Extension { get; set; }

        public override bool Execute()
        {
            var bundle = new MultipartFormDataContent(
                "--0a7e8441d64b4bf89086b85e59523b7d");

            foreach (var asset in PublishBlazorBootStaticWebAsset)
            {
                var name =
Path.GetFileName(asset.GetMetadata("RelativePath"));
                var fileContents = File.OpenRead(asset.ItemSpec);
                var content = new StreamContent(fileContents);
                var disposition = new ContentDispositionHeaderValue("form-
data");
                disposition.Name = name;
                disposition.FileName = name;
                content.Headers.ContentDisposition = disposition;
                var contentType = Path.GetExtension(name) switch
                {
                    ".js" => "text/javascript",
                    ".wasm" => "application/wasm",
```

```
                    _ => "application/octet-stream"
                };
                content.Headers.ContentType =
                    MediaTypeHeaderValue.Parse(contentType);
                bundle.Add(content);
            }

            using (var output = File.Open(BundlePath,
FileMode.OpenOrCreate))
            {
                output.SetLength(0);

bundle.CopyToAsync(output).ConfigureAwait(false).GetAwaiter()
                    .GetResult();
                output.Flush(true);
            }

            var bundleItem = new TaskItem(BundlePath);
            bundleItem.SetMetadata("RelativePath", "app.bundle");
            bundleItem.SetMetadata("ExtensionName", "multipart");

            Extension = new ITaskItem[] { bundleItem };

            return true;
        }
    }
}
```

Author a NuGet package to automatically transform the publish output

Generate a NuGet package with MSBuild targets that are automatically included when the package is referenced:

- Create a new Razor class library (RCL) project.
- Create a targets file following NuGet conventions to automatically import the package in consuming projects. For example, create `build\net6.0\{PACKAGE ID}.targets`, where `{PACKAGE ID}` is the package identifier of the package.
- Collect the output from the class library containing the MSBuild task and confirm the output is packed in the right location.
- Add the necessary MSBuild code to attach to the Blazor pipeline and invoke the MSBuild task to generate the bundle.

The approach described in this section only uses the package to deliver targets and content, which is different from most packages where the package includes a library DLL.

> ⚠ **Warning**
>
> The sample package described in this section demonstrates how to customize the Blazor publish process. **The sample NuGet package is for use as a local demonstration only. Using this package in production is not supported.**

> ⓘ **Note**
>
> The NuGet package for the examples in this article are named after the package provided by Microsoft, `Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle`. For guidance on naming and producing your own NuGet package, see the following NuGet articles:
>
> - Package authoring best practices
> - Package ID prefix reservation

`Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle/Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.csproj`:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Razor">

  <PropertyGroup>
    <NoWarn>NU5100</NoWarn>
    <TargetFramework>net6.0</TargetFramework>
    <ImplicitUsings>enable</ImplicitUsings>
    <Nullable>enable</Nullable>
    <Description>
      Sample demonstration package showing how to customize the Blazor
publish
      process. Using this package in production is not supported!
    </Description>
    <IsPackable>true</IsPackable>
    <IsShipping>true</IsShipping>
    <IncludeBuildOutput>false</IncludeBuildOutput>
  </PropertyGroup>

  <ItemGroup>
    <None Update="build\**"
          Pack="true"
          PackagePath="%(Identity)" />
    <Content Include="_._"
             Pack="true"
             PackagePath="lib\net6.0\_._" />
  </ItemGroup>
```

```
  <Target Name="GetTasksOutputDlls"
          BeforeTargets="CoreCompile">
    <MSBuild
Projects="..\Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tas
ks\Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tasks.csproj"
             Targets="Publish;PublishItemsOutputGroup"
             Properties="Configuration=Release">
      <Output TaskParameter="TargetOutputs"
              ItemName="_TasksProjectOutputs" />
    </MSBuild>
    <ItemGroup>
      <Content Include="@(_TasksProjectOutputs)"
               Condition="'%(_TasksProjectOutputs.Extension)' == '.dll'"
               Pack="true"
               PackagePath="tasks\%(_TasksProjectOutputs.TargetPath)"
               KeepMetadata="Pack;PackagePath" />
    </ItemGroup>
  </Target>

</Project>
```

> **Note**
>
> The `<NoWarn>NU5100</NoWarn>` property in the preceding example suppresses the warning about the assemblies placed in the `tasks` folder. For more information, see NuGet Warning NU5100.

Add a `.targets` file to wire up the MSBuild task to the build pipeline. In this file, the following goals are accomplished:

- Import the task into the build process. Note that the path to the DLL is relative to the ultimate location of the file in the package.
- The `ComputeBlazorExtensionsDependsOn` property attaches the custom target to the Blazor WebAssembly pipeline.
- Capture the `Extension` property on the task output and add it to `BlazorPublishExtension` to tell Blazor about the extension. Invoking the task in the target produces the bundle. The list of published files is provided by the Blazor WebAssembly pipeline in the `PublishBlazorBootStaticWebAsset` item group. The bundle path is defined using the `IntermediateOutputPath` (typically inside the `obj` folder). Ultimately, the bundle is copied automatically to the correct location in the publish output folder (for example, `bin\Release\net6.0\publish`).

When the package is referenced, it generates a bundle of the Blazor files during publish.

`Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle/build/net6.0/Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.targets`:

XML

```
<Project>
  <UsingTask

TaskName="Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tasks.BundleBlazorAssets"

AssemblyFile="$(MSBuildThisProjectFileDirectory)..\..\tasks\Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.Tasks.dll" />

  <PropertyGroup>
    <ComputeBlazorExtensionsDependsOn>
      $(ComputeBlazorExtensionsDependsOn);_BundleBlazorDlls
    </ComputeBlazorExtensionsDependsOn>
  </PropertyGroup>

  <Target Name="_BundleBlazorDlls">
    <BundleBlazorAssets
      PublishBlazorBootStaticWebAsset="@(PublishBlazorBootStaticWebAsset)"
      BundlePath="$(IntermediateOutputPath)bundle.multipart">
      <Output TaskParameter="Extension"
              ItemName="BlazorPublishExtension"/>
    </BundleBlazorAssets>
  </Target>

</Project>
```

Automatically bootstrap Blazor from the bundle

The NuGet package leverages JavaScript (JS) initializers to automatically bootstrap a Blazor WebAssembly app from the bundle instead of using individual DLL files. JS initializers are used to change the Blazor boot resource loader and use the bundle.

To create a JS initializer, add a JS file with the name `{NAME}.lib.module.js` to the `wwwroot` folder of the package project, where the `{NAME}` placeholder is the package identifier. For example, the file for the Microsoft package is named `Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.lib.module.js`. The exported functions `beforeWebAssemblyStart` and `afterWebAssemblyStarted` handle loading.

The JS initializers:

- Detect if the Publish Extension is available by checking for `extensions.multipart`, which is the extension name (`ExtensionName`) provided in the Create an MSBuild task to customize the list of published files and define new extensions section.
- Download the bundle and parse the contents into a resources map using generated object URLs.
- Update the boot resource loader (options.loadBootResource) with a custom function that resolves the resources using the object URLs.
- After the app has started, revoke the object URLs to release memory in the `afterWebAssemblyStarted` function.

`Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle/wwwroot/Microsoft.AspNetCore.Components.WebAssembly.MultipartBundle.lib.module.js`:

JavaScript

```
const resources = new Map();

export async function beforeWebAssemblyStart(options, extensions) {
  if (!extensions || !extensions.multipart) {
    return;
  }

  try {
    const integrity = extensions.multipart['app.bundle'];
    const bundleResponse =
      await fetch('app.bundle', { integrity: integrity, cache: 'no-cache'
});
    const bundleFromData = await bundleResponse.formData();
    for (let value of bundleFromData.values()) {
      resources.set(value, URL.createObjectURL(value));
    }
    options.loadBootResource = function (type, name, defaultUri, integrity)
{
      return resources.get(name) ?? null;
    }
  } catch (error) {
    console.log(error);
  }
}

export async function afterWebAssemblyStarted(blazor) {
  for (const [_, url] of resources) {
    URL.revokeObjectURL(url);
  }
}
```

Serve the bundle from the host server app

Due to security restrictions, ASP.NET Core doesn't serve the `app.bundle` file. A request processing helper is required to serve the file when it's requested by clients.

> **Note**
>
> Since the same optimizations are transparently applied to the Publish Extensions that are applied to the app's files, the `app.bundle.gz` and `app.bundle.br` compressed asset files are produced automatically on publish.

Place C# code in `Program.cs` of the **Server** project immediately before the line that sets the fallback file to `index.html` (`app.MapFallbackToFile("index.html");`) to respond to a request for the bundle file (for example, `app.bundle`):

C#

```
app.MapGet("app.bundle", (HttpContext context) =>
{
    string? contentEncoding = null;
    var contentType =
        "multipart/form-data; boundary=\"-
-0a7e8441d64b4bf89086b85e59523b7d\"";
    var fileName = "app.bundle";

    var acceptEncodings = context.Request.Headers.AcceptEncoding;

    if (Microsoft.Net.Http.Headers.StringWithQualityHeaderValue
        .StringWithQualityHeaderValue
        .TryParseList(acceptEncodings, out var encodings))
    {
        if (encodings.Any(e => e.Value == "br"))
        {
            contentEncoding = "br";
            fileName += ".br";
        }
        else if (encodings.Any(e => e.Value == "gzip"))
        {
            contentEncoding = "gzip";
            fileName += ".gz";
        }
    }

    if (contentEncoding != null)
    {
        context.Response.Headers.ContentEncoding = contentEncoding;
    }

    return Results.File(
        app.Environment.WebRootFileProvider.GetFileInfo(fileName)
```

```
            .CreateReadStream(), contentType);
});
```

The content type matches the type defined earlier in the build task. The endpoint checks for the content encodings accepted by the browser and serves the optimal file, Brotli (`.br`) or Gzip (`.gz`).

ASP.NET Core Blazor with Entity Framework Core (EF Core)

Article • 10/28/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to use Entity Framework Core (EF Core) in server-side Blazor apps.

Server-side Blazor is a stateful app framework. The app maintains an ongoing connection to the server, and the user's state is held in the server's memory in a *circuit*. One example of user state is data held in dependency injection (DI) service instances that are scoped to the circuit. The unique application model that Blazor provides requires a special approach to use Entity Framework Core.

> **Note**
>
> This article addresses EF Core in server-side Blazor apps. Blazor WebAssembly apps run in a WebAssembly sandbox that prevents most direct database connections. Running EF Core in Blazor WebAssembly is beyond the scope of this article.

This guidance applies to components that adopt interactive server-side rendering (interactive SSR) in a Blazor Web App.

Secure authentication flow required for production apps

This article uses a local database that doesn't require user authentication. Production apps should use the most secure authentication flow available. For more information on authentication for deployed test and production Blazor apps, see the articles in the Blazor *Security and Identity* node.

For Microsoft Azure services, we recommend using *managed identities*. Managed identities securely authenticate to Azure services without storing credentials in app code. For more information, see the following resources:

- What are managed identities for Azure resources? (Microsoft Entra documentation)
- Azure services documentation
  - Managed identities in Microsoft Entra for Azure SQL
  - How to use managed identities for App Service and Azure Functions

Sample app

The sample app was built as a reference for server-side Blazor apps that use EF Core. The sample app includes a grid with sorting and filtering, delete, add, and update operations.

The sample demonstrates use of EF Core to handle optimistic concurrency. However, native database-generated concurrency tokens aren't supported for SQLite databases, which is the database provider for the sample app. To demonstrate concurrency with the sample app, adopt a different database provider that supports database-generated concurrency tokens (for example, the SQL Server provider).

View or download sample code (how to download): Select the folder that matches the version of .NET that you're adopting. Within the version folder, access the sample named `BlazorWebAppEFCore`.

The sample uses a local SQLite database so that it can be used on any platform. The sample also configures database logging to show the SQL queries that are generated. This is configured in `appsettings.Development.json`:

JSON

```
{
  "DetailedErrors": true,
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning",
      "Microsoft.Hosting.Lifetime": "Information",
      "Microsoft.EntityFrameworkCore.Database.Command": "Information"
    }
  }
}
```

The grid, add, and view components use the "context-per-operation" pattern, where a context is created for each operation. The edit component uses the "context-per-

component" pattern, where a context is created for each component.

> **Note**
>
> Some of the code examples in this topic require namespaces and services that aren't shown. To inspect the fully working code, including the required @using and @inject directives for Razor examples, see the sample app.

Build a Blazor movie database app tutorial

For a tutorial experience building an app that uses EF Core to work with a database, see Build a Blazor movie database app (Overview). The tutorial shows you how to create a Blazor Web App that can display and manage movies in a movie database.

Database access

EF Core relies on a DbContext as the means to configure database access and act as a *unit of work*. EF Core provides the AddDbContext extension for ASP.NET Core apps that registers the context as a *scoped* service. In server-side Blazor apps, scoped service registrations can be problematic because the instance is shared across components within the user's circuit. DbContext isn't thread safe and isn't designed for concurrent use. The existing lifetimes are inappropriate for these reasons:

- **Singleton** shares state across all users of the app and leads to inappropriate concurrent use.
- **Scoped** (the default) poses a similar issue between components for the same user.
- **Transient** results in a new instance per request; but as components can be long-lived, this results in a longer-lived context than may be intended.

The following recommendations are designed to provide a consistent approach to using EF Core in server-side Blazor apps.

- Consider using one context per operation. The context is designed for fast, low overhead instantiation:

```
C#
```

```
using var context = new MyContext();

return await context.MyEntities.ToListAsync();
```

- Use a flag to prevent multiple concurrent operations:

  ```C#
  if (Loading)
  {
      return;
  }

  try
  {
      Loading = true;

      ...
  }
  finally
  {
      Loading = false;
  }
  ```

  Place operations after the `Loading = true;` line in the `try` block.

  Thread safety isn't a concern, so loading logic doesn't require locking database records. The loading logic is used to disable UI controls so that users don't inadvertently select buttons or update fields while data is fetched.

- If there's any chance that multiple threads may access the same code block, inject a factory and make a new instance per operation. Otherwise, injecting and using the context is usually sufficient.

- For longer-lived operations that take advantage of EF Core's change tracking or concurrency control, scope the context to the lifetime of the component.

New `DbContext` instances

The fastest way to create a new DbContext instance is by using `new` to create a new instance. However, there are scenarios that require resolving additional dependencies:

- Using DbContextOptions to configure the context.
- Using a connection string per DbContext, such as when you use ASP.NET Core's Identity model. For more information, see Multi-tenancy (EF Core documentation).

> ⚠ **Warning**
>
> Don't store app secrets, connection strings, credentials, passwords, personal identification numbers (PINs), private C#/.NET code, or private keys/tokens in

client-side code, which is ***always insecure***. In test/staging and production environments, server-side Blazor code and web APIs should use secure authentication flows that avoid maintaining credentials within project code or configuration files. Outside of local development testing, we recommend avoiding the use of environment variables to store sensitive data, as environment variables aren't the most secure approach. For local development testing, the Secret Manager tool is recommended for securing sensitive data. For more information, see Securely maintain sensitive data and credentials.

The recommended approach to create a new DbContext with dependencies is to use a factory. EF Core 5.0 or later provides a built-in factory for creating new contexts.

The following example configures SQLite and enables data logging. The code uses an extension method (`AddDbContextFactory`) to configure the database factory for DI and provide default options:

C#

```
builder.Services.AddDbContextFactory<ContactContext>(opt =>
    opt.UseSqlite($"Data Source={nameof(ContactContext.ContactsDb)}.db"));
```

The factory is injected into components and used to create new `DbContext` instances.

In the home page of the sample app, `IDbContextFactory<ContactContext>` is injected into the component:

razor

```
@inject IDbContextFactory<ContactContext> DbFactory
```

A `DbContext` is created using the factory (`DbFactory`) to delete a contact in the `DeleteContactAsync` method:

razor

```
private async Task DeleteContactAsync()
{
    using var context = DbFactory.CreateDbContext();
    Filters.Loading = true;

    if (Wrapper is not null && context.Contacts is not null)
    {
        var contact = await context.Contacts
            .FirstAsync(c => c.Id == Wrapper.DeleteRequestId);
```

```
        if (contact is not null)
        {
            context.Contacts?.Remove(contact);
            await context.SaveChangesAsync();
        }
    }

    Filters.Loading = false;

    await ReloadAsync();
}
```

> **Note**
>
> `Filters` is an injected `IContactFilters`, and `Wrapper` is a component reference to the `GridWrapper` component. See the `Home` component (`Components/Pages/Home.razor`) in the sample app.

Scope to the component lifetime

You may wish to create a DbContext that exists for the lifetime of a component. This allows you to use it as a unit of work and take advantage of built-in features, such as change tracking and concurrency resolution.

You can use the factory to create a context and track it for the lifetime of the component. First, implement IDisposable and inject the factory as shown in the `EditContact` component (`Components/Pages/EditContact.razor`):

razor

```
@implements IDisposable
@inject IDbContextFactory<ContactContext> DbFactory
```

The sample app ensures the context is disposed when the component is disposed:

C#

```
public void Dispose() => Context?.Dispose();
```

Finally, OnInitializedAsync is overridden to create a new context. In the sample app, OnInitializedAsync loads the contact in the same method:

C#

```
protected override async Task OnInitializedAsync()
{
    Busy = true;

    try
    {
        Context = DbFactory.CreateDbContext();

        if (Context is not null && Context.Contacts is not null)
        {
            var contact = await Context.Contacts.SingleOrDefaultAsync(c =>
c.Id == ContactId);

            if (contact is not null)
            {
                Contact = contact;
            }
        }
    }
    finally
    {
        Busy = false;
    }
}
```

Enable sensitive data logging

EnableSensitiveDataLogging includes application data in exception messages and framework logging. The logged data can include the values assigned to properties of entity instances and parameter values for commands sent to the database. Logging data with EnableSensitiveDataLogging is a **security risk**, as it may expose passwords and other Personally Identifiable Information (PII) when it logs SQL statements executed against the database.

We recommend only enabling EnableSensitiveDataLogging for development and testing:

C#

```
#if DEBUG
    services.AddDbContextFactory<ContactContext>(opt =>
        opt.UseSqlite($"Data Source={nameof(ContactContext.ContactsDb)}.db")
        .EnableSensitiveDataLogging());
#else
    services.AddDbContextFactory<ContactContext>(opt =>
        opt.UseSqlite($"Data Source=
```

```
{nameof(ContactContext.ContactsDb)}.db"));
#endif
```

ASP.NET Core Blazor advanced scenarios (render tree construction)

Article • 10/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

This article describes the advanced scenario for building Blazor render trees manually with RenderTreeBuilder.

> **⚠ Warning**
>
> Use of RenderTreeBuilder to create components is an *advanced scenario*. A malformed component (for example, an unclosed markup tag) can result in undefined behavior. Undefined behavior includes broken content rendering, loss of app features, and ***compromised security***.

Manually build a render tree (`RenderTreeBuilder`)

RenderTreeBuilder provides methods for manipulating components and elements, including building components manually in C# code.

Consider the following `PetDetails` component, which can be manually rendered in another component.

`PetDetails.razor`:

```razor
<h2>Pet Details</h2>

<p>@PetDetailsQuote</p>

@code
```

```
{
    [Parameter]
    public string? PetDetailsQuote { get; set; }
}
```

In the following `BuiltContent` component, the loop in the `CreateComponent` method generates three `PetDetails` components.

In RenderTreeBuilder methods with a sequence number, sequence numbers are source code line numbers. The Blazor difference algorithm relies on the sequence numbers corresponding to distinct lines of code, not distinct call invocations. When creating a component with RenderTreeBuilder methods, hardcode the arguments for sequence numbers. **Using a calculation or counter to generate the sequence number can lead to poor performance.** For more information, see the Sequence numbers relate to code line numbers and not execution order section.

`BuiltContent.razor`:

razor

```
@page "/built-content"

<PageTitle>Built Content</PageTitle>

<h1>Built Content Example</h1>

<div>
    @CustomRender
</div>

<button @onclick="RenderComponent">
    Create three Pet Details components
</button>

@code {
    private RenderFragment? CustomRender { get; set; }

    private RenderFragment CreateComponent() => builder =>
    {
        for (var i = 0; i < 3; i++)
        {
            builder.OpenComponent(0, typeof(PetDetails));
            builder.AddAttribute(1, "PetDetailsQuote", "Someone's best
friend!");
            builder.CloseComponent();
        }
    };
```

```
    private void RenderComponent() => CustomRender = CreateComponent();
}
```

> ⚠ **Warning**
>
> The types in Microsoft.AspNetCore.Components.RenderTree allow processing of the *results* of rendering operations. These are internal details of the Blazor framework implementation. These types should be considered *unstable* and subject to change in future releases.

Sequence numbers relate to code line numbers and not execution order

Razor component files (`.razor`) are always compiled. Executing compiled code has a potential advantage over interpreting code because the compile step that yields the compiled code can be used to inject information that improves app performance at runtime.

A key example of these improvements involves *sequence numbers*. Sequence numbers indicate to the runtime which outputs came from which distinct and ordered lines of code. The runtime uses this information to generate efficient tree diffs in linear time, which is far faster than is normally possible for a general tree diff algorithm.

Consider the following Razor component file (`.razor`):

razor

```
@if (someFlag)
{
    <text>First</text>
}

Second
```

The preceding Razor markup and text content compiles into C# code similar to the following:

C#

```
if (someFlag)
{
    builder.AddContent(0, "First");
}
```

```
builder.AddContent(1, "Second");
```

When the code executes for the first time and `someFlag` is `true`, the builder receives the sequence in the following table.

Expand table

Sequence	Type	Data
0	Text node	First
1	Text node	Second

Imagine that `someFlag` becomes `false` and the markup is rendered again. This time, the builder receives the sequence in the following table.

Expand table

Sequence	Type	Data
1	Text node	Second

When the runtime performs a diff, it sees that the item at sequence `0` was removed, so it generates the following trivial *edit script* with a single step:

- Remove the first text node.

The problem with generating sequence numbers programmatically

Imagine instead that you wrote the following render tree builder logic:

C#

```
var seq = 0;

if (someFlag)
{
    builder.AddContent(seq++, "First");
}

builder.AddContent(seq++, "Second");
```

The first output is reflected in the following table.

Expand table

Sequence	Type	Data
0	Text node	First
1	Text node	Second

This outcome is identical to the prior case, so no negative issues exist. `someFlag` is `false` on the second rendering, and the output is seen in the following table.

Expand table

Sequence	Type	Data
0	Text node	Second

This time, the diff algorithm sees that *two* changes have occurred. The algorithm generates the following edit script:

- Change the value of the first text node to `Second`.
- Remove the second text node.

Generating the sequence numbers has lost all the useful information about where the `if/else` branches and loops were present in the original code. This results in a diff **twice as long** as before.

This is a trivial example. In more realistic cases with complex and deeply nested structures, and especially with loops, the performance cost is usually higher. Instead of immediately identifying which loop blocks or branches have been inserted or removed, the diff algorithm must recurse deeply into the render trees. This usually results in building longer edit scripts because the diff algorithm is misinformed about how the old and new structures relate to each other.

Guidance and conclusions

- App performance suffers if sequence numbers are generated dynamically.
- The necessary information doesn't exist to permit the framework to generate sequence numbers automatically at runtime unless the information is captured at compile time.
- Don't write long blocks of manually-implemented RenderTreeBuilder logic. Prefer `.razor` files and allow the compiler to deal with the sequence numbers. If you're unable to avoid manual RenderTreeBuilder logic, split long blocks of code into

smaller pieces wrapped in OpenRegion/CloseRegion calls. Each region has its own separate space of sequence numbers, so you can restart from zero (or any other arbitrary number) inside each region.

- If sequence numbers are hardcoded, the diff algorithm only requires that sequence numbers increase in value. The initial value and gaps are irrelevant. One legitimate option is to use the code line number as the sequence number, or start from zero and increase by ones or hundreds (or any preferred interval).
- For loops, the sequence numbers should increase in your source code, not in terms of runtime behavior. The fact that, at runtime, the numbers repeat is how the diffing system realises you're in a loop.
- Blazor uses sequence numbers, while other tree-diffing UI frameworks don't use them. Diffing is far faster when sequence numbers are used, and Blazor has the advantage of a compile step that deals with sequence numbers automatically for developers authoring `.razor` files.

Tutorial: Create an ASP.NET Core app with Angular in Visual Studio

Article • 11/08/2024

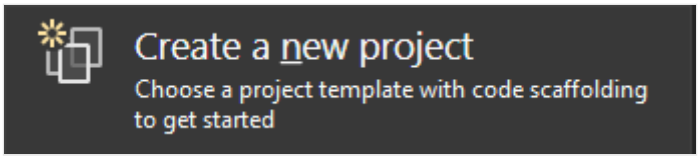
In this article, you learn how to build an ASP.NET Core project to act as an API backend and an Angular project to act as the UI.

Visual Studio includes ASP.NET Core Single Page Application (SPA) templates that support Angular and React. The templates provide a built-in Client App folder in your ASP.NET Core projects that contains the base files and folders of each framework.

You can use the method described in this article to create ASP.NET Core Single Page Applications that:

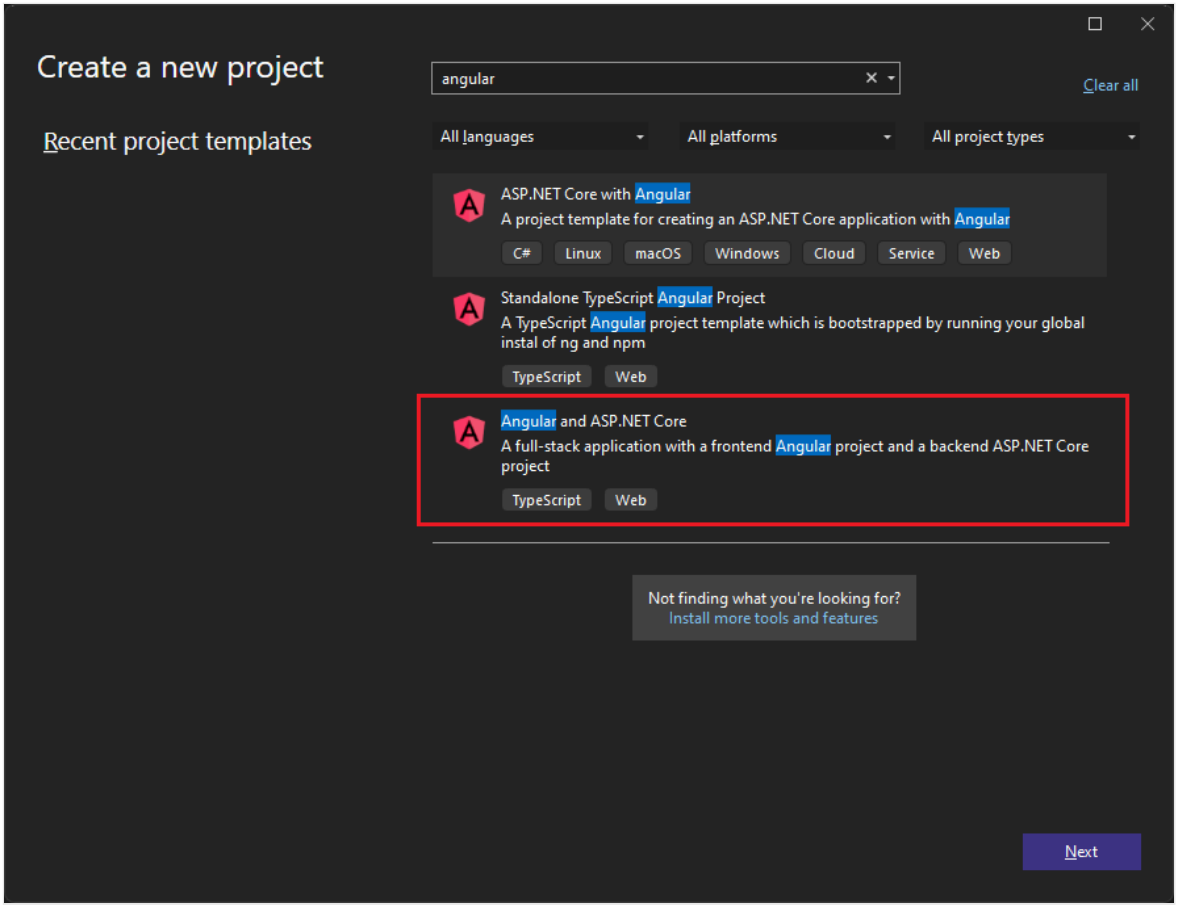
- Put the client app in a separate project, outside from the ASP.NET Core project
- Create the client project based on the framework CLI installed on your computer

> **Note**
>
> This article describes the project creation process using the updated template in Visual Studio 2022 version 17.8.



Prerequisites

Make sure to install the following:

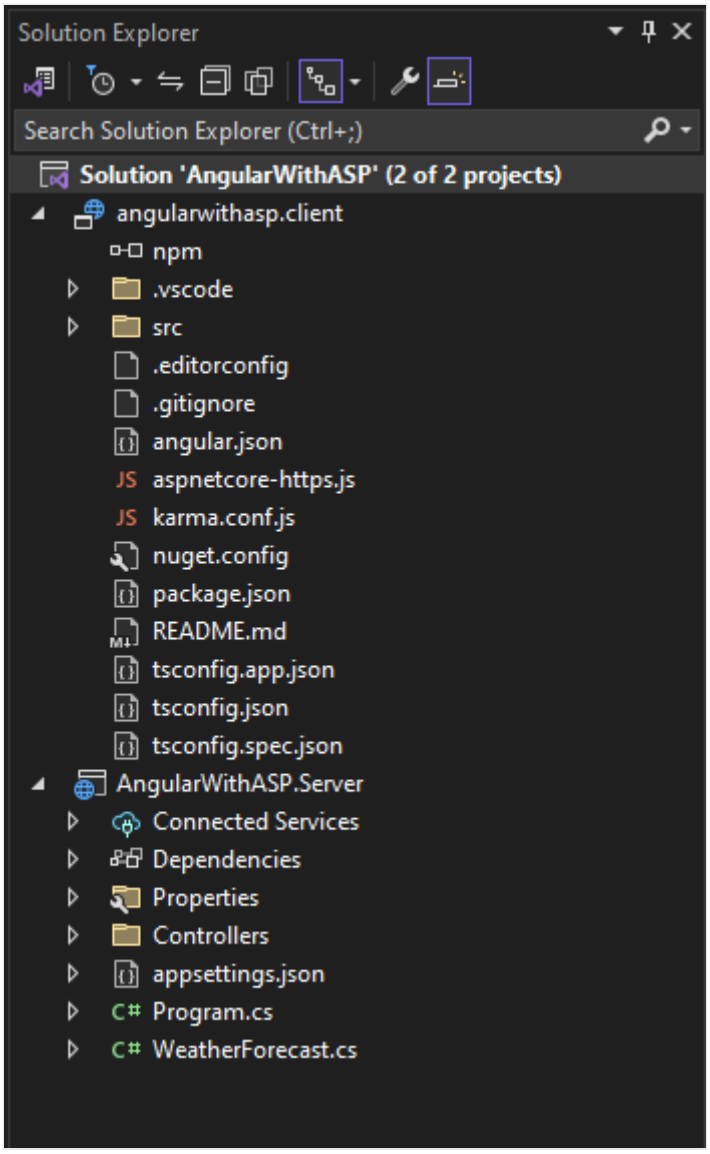


- Visual Studio 2022 version 17.8 or later with the **ASP.NET and web development** workload installed. Go to the Visual Studio downloads page to install it for free. If you need to install the workload and already have Visual Studio, go to **Tools** > **Get Tools and Features...**, which opens the Visual Studio Installer. Choose the **ASP.NET and web development** workload, then choose **Modify**.
- npm (https://www.npmjs.com/), which is included with Node.js
- Angular CLI (https://angular.dev/tools/cli), which can be the version of your choice.

Create the frontend app

1. In the Start window (choose **File** > **Start Window** to open), select **Create a new project**.

2. Search for Angular in the search bar at the top and then select **Angular and ASP.NET Core**.

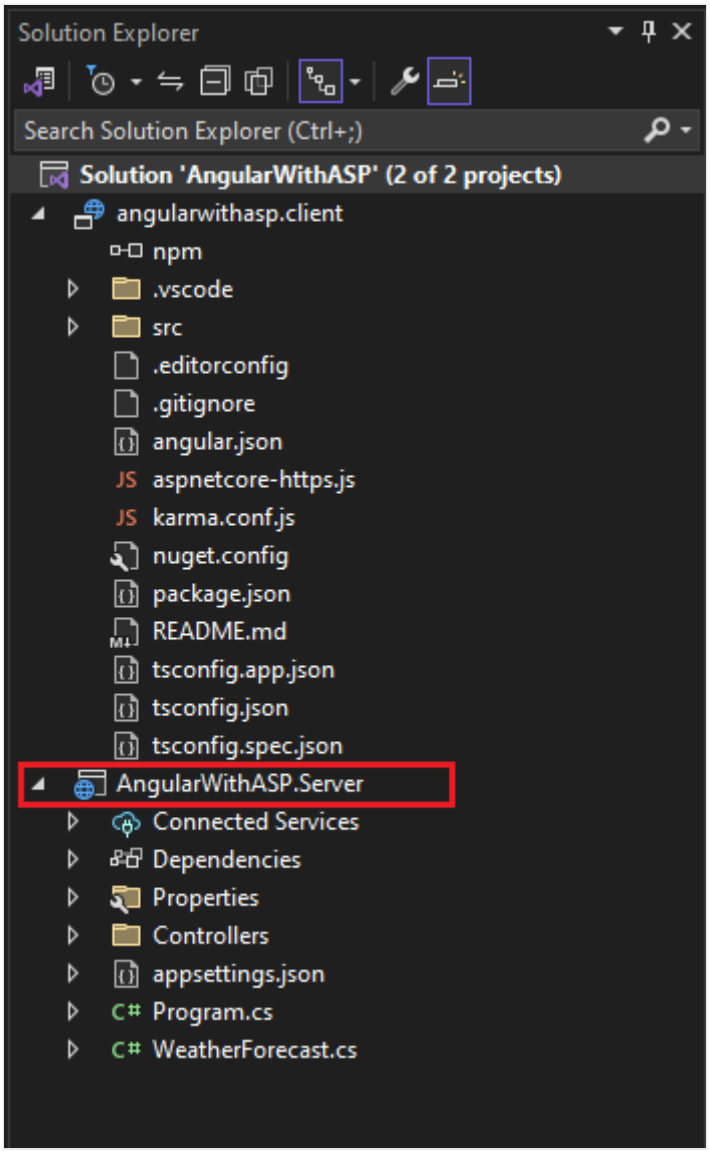


3. Name the project **AngularWithASP** and then select **Next**.

   In the Additional Information dialog, make sure that **Configure for HTTPS** is enabled. In most scenarios, leave the other settings at the default values.

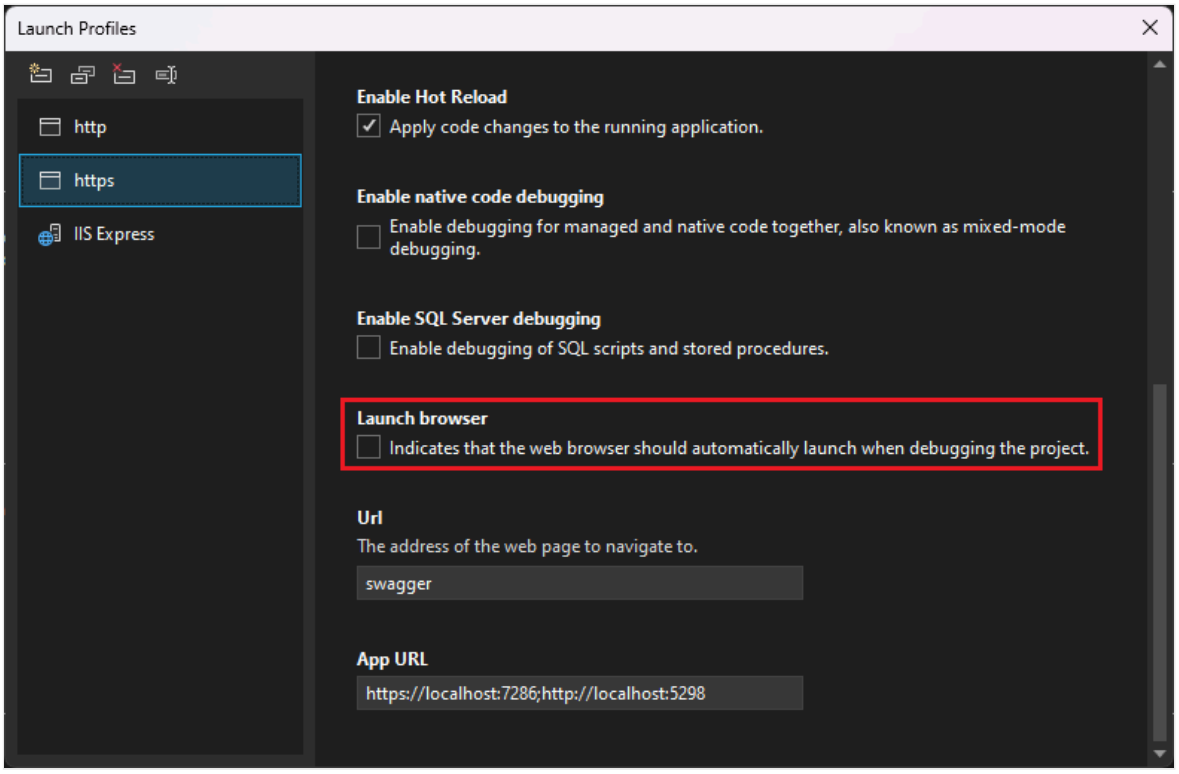
4. Select **Create**.

   Solution Explorer shows the following::



Compared to the standalone Angular template, you see some new and modified files for integration with ASP.NET Core:

- aspnetcore-https.js
- proxy.conf.js
- package.json(modified)
- angular.json(modified)
- app.components.ts
- app.module.ts



For more information on some of these project files, see Next steps.

Set the project properties

1. In Solution Explorer, right-click the **AngularWithASP.Server** project and choose **Properties**.

2. In the Properties page, open the **Debug** tab and select **Open debug launch profiles UI** option. Uncheck the **Launch Browser** option for the **https** profile or the profile named after the ASP.NET Core project, if present.

This value prevents opening the web page with the source weather data.

> ⓘ Note
>
> In Visual Studio, `launch.json` stores the startup settings associated with the **Start** button in the Debug toolbar. `launch.json` must be located under the `.vscode` folder.

3. Right-click the solution in Solution Explorer and select **Properties**. Verify that the Startup project settings are set to **Multiple projects**, and that the Action for both projects is set to **Start**.

Start the project

Press **F5** or select the **Start** button at the top of the window to start the app. Two command prompts appear:

- The ASP.NET Core API project running
- The Angular CLI running the ng start command

> ⓘ Note
>
> Check console output for messages. For example there might be a message to update Node.js.

The Angular app appears and is populated via the API. If you don't see the app, see Troubleshooting.

Publish the project

Starting in Visual Studio 2022 version 17.3, you can publish the integrated solution using the Visual Studio Publish tool.

> **Note**
>
> To use publish, create your JavaScript project using Visual Studio 2022 version 17.3 or later.

1. In Solution Explorer, right-click the **AngularWithASP.Server** project and select **Add** > **Project Reference**.

   Make sure the **angularwithasp.client** project is selected.

2. Choose **OK**.

3. Right-click the ASP.NET Core project again and select **Edit Project File**.

   This opens the `.csproj` file for the project.

4. In the `.csproj` file, make sure the project reference includes a `<ReferenceOutputAssembly>` element with the value set to `false`.

   This reference should look like the following.

   XML

   ```
    <ProjectReference
   Include="..\angularwithasp.client\angularwithasp.client.esproj">
      <ReferenceOutputAssembly>false</ReferenceOutputAssembly>
    </ProjectReference>
   ```

5. Right-click the ASP.NET Core project and choose **Reload Project** if that option is available.

6. In *Program.cs*, make sure the following code is present.

   C#

   ```
   app.UseDefaultFiles();
   app.UseStaticFiles();
   ```

```
// Configure the HTTP request pipeline.
if (app.Environment.IsDevelopment())
{
   app.UseSwagger();
   app.UseSwaggerUI();
}
```

7. To publish, right click the ASP.NET Core project, choose **Publish**, and select options to match your desired publish scenario, such as Azure, publish to a folder, etc.

   The publish process takes more time than it does for just an ASP.NET Core project, since the `npm run build` command gets invoked when publishing. The BuildCommand runs `npm run build` by default.

   If you publish to a folder, see ASP.NET Core directory structure for more information on the files added to the *publish* folder.

Troubleshooting

Proxy error

You may see the following error:

Windows Command Prompt

```
[HPM] Error occurred while trying to proxy request /weatherforecast from
localhost:4200 to https://localhost:5001 (ECONNREFUSED)
(https://nodejs.org/api/errors.html#errors_common_system_errors)
```

If you see this issue, most likely the frontend started before the backend.

- Once you see the backend command prompt up and running, just refresh the Angular app in the browser.
- Also, verify that the backend is configured to start before the front end. To verify, select the solution in Solution Explorer, choose **Properties** from the **Project menu**. Next, select **Configure Startup Projects** and make sure that the backend ASP.NET Core project is first in the list. If it's not first, select the project and use the Up arrow button to make it the first project in the launch list.

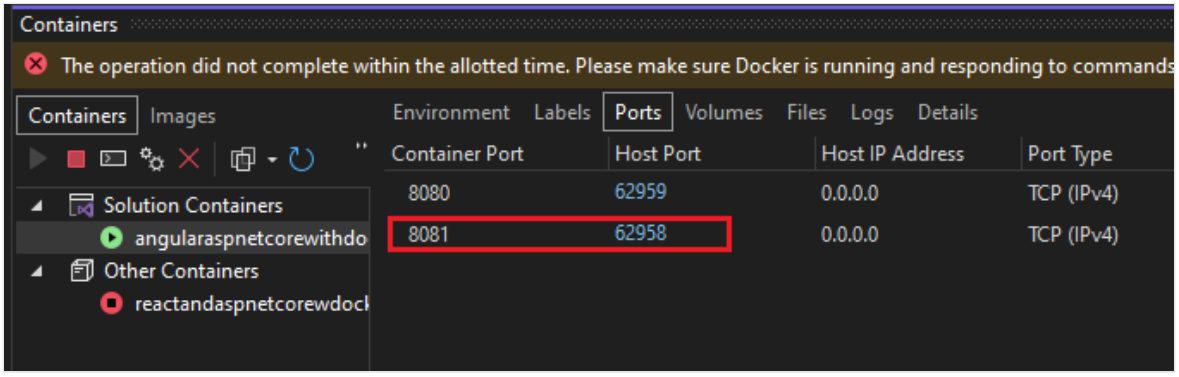
Verify port

If the weather data doesn't load correctly, you may also need to verify that your ports are correct.

1. Go to the `launchSettings.json` file in your ASP.NET Core project (in the *Properties* folder). Get the port number from the `applicationUrl` property.

   If there are multiple `applicationUrl` properties, look for one using an `https` endpoint. It should look similar to `https://localhost:7049`.

2. Then, go to the `proxy.conf.js` file for your Angular project (look in the *src* folder). Update the target property to match the `applicationUrl` property in *launchSettings.json*. When you update it, that value should look similar to this:



```
JavaScript

target: 'https://localhost:7049',
```

Docker

If you create the project with Docker support enabled, take the following steps:

1. After the app loads, get the Docker HTTPS port using the Containers window in Visual Studio. Check the **Environment** or **Ports** tab.

2. Open the `proxy.conf.js` file for the Angular project. Update the `target` variable to match the HTTPS port in the Containers window. For example, in the following code:

```
JavaScript

const target = env.ASPNETCORE_HTTPS_PORT ?
`https://localhost:${env.ASPNETCORE_HTTPS_PORT}` :
   env.ASPNETCORE_URLS ? env.ASPNETCORE_URLS.split(';')[0] :
'https://localhost:7209';
```

change `https://localhost:7209` to the matching HTTPS port (in this example, `https://localhost:62958`).

3. Restart the app.

Next steps

For more information about SPA applications in ASP.NET Core, see the Angular section under Developing Single Page Apps. The linked article provides additional context for project files such as *aspnetcore-https.js* and *proxy.conf.js*, although details of the implementation are different due to project template differences. For example, instead of a ClientApp folder, the Angular files are contained in a separate project.

For MSBuild information specific to the client project, see MSBuild properties for JSPS.

Tutorial: Create an ASP.NET Core app with React in Visual Studio

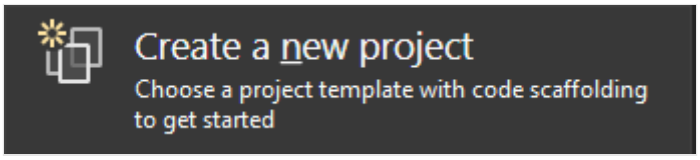
Article • 11/06/2024

In this article, you learn how to build an ASP.NET Core project to act as an API backend and a React project to act as the UI.

Currently, Visual Studio includes ASP.NET Core Single Page Application (SPA) templates that support Angular and React. The templates provide a built-in Client App folder in your ASP.NET Core projects that contains the base files and folders of each framework.

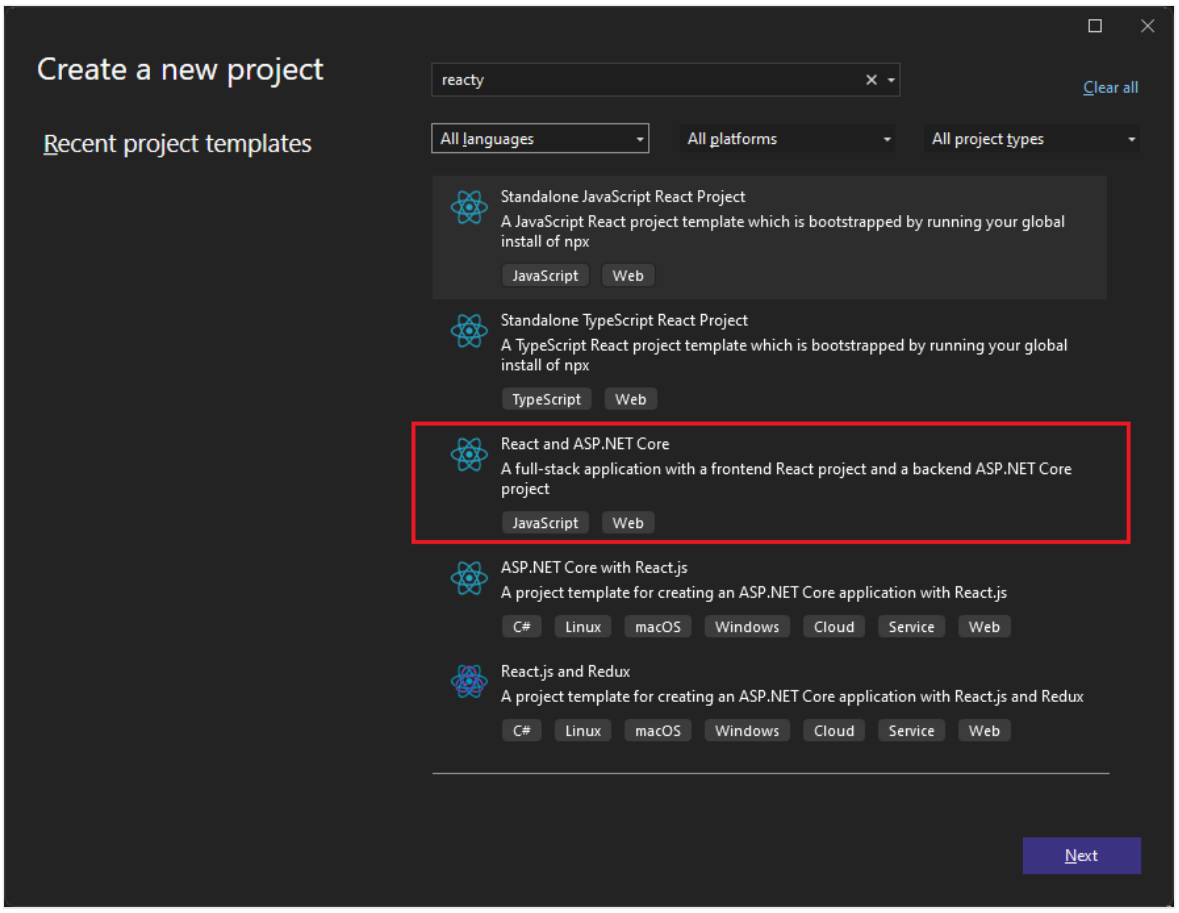
You can use the method described in this article to create ASP.NET Core Single Page Applications that:

- Put the client app in a separate project, outside from the ASP.NET Core project
- Create the client project based on the framework CLI installed on your computer



> **Note**
>
> This article describes the project creation process using the updated template in Visual Studio 2022 version 17.11, which uses the Vite CLI.

Prerequisites

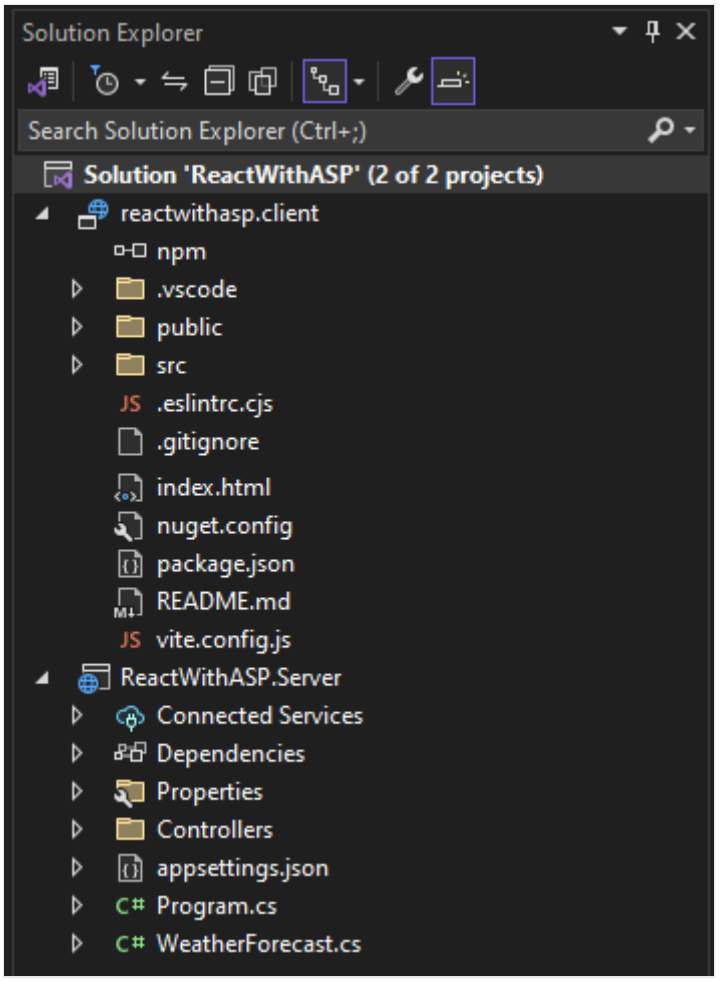


- Visual Studio 2022 version 17.11 or later with the **ASP.NET and web development** workload installed. Go to the Visual Studio downloads page to install it for free. If you need to install the workload and already have Visual Studio, go to **Tools** > **Get Tools and Features...**, which opens the Visual Studio Installer. Choose the **ASP.NET and web development** workload, then choose **Modify**.
- npm (https://www.npmjs.com/), which is included with Node.js

Create the frontend app

1. In the Start window, select **Create a new project**.

2. Search for React in the search bar at the top and then select **React and ASP.NET Core**. This template is a JavaScript template.



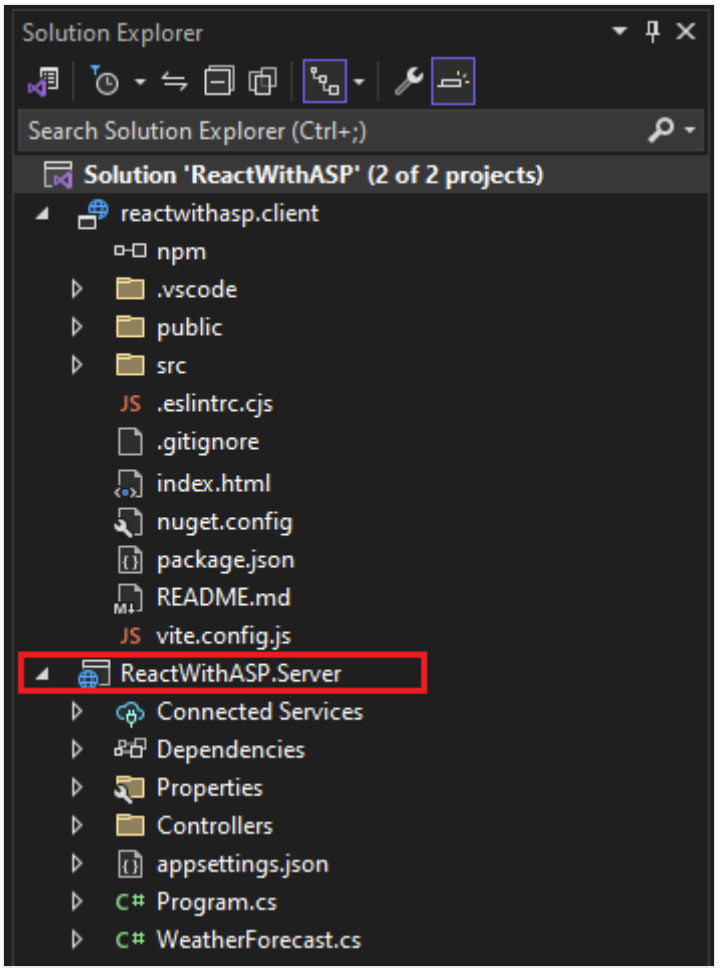
3. Name the project **ReactWithASP** and then select **Next**.

   In the Additional Information dialog, make sure that **Configure for HTTPS** is enabled. In most scenarios, leave the other settings at the default values.

4. Select **Create**.

   Solution Explorer shows the following project information:

Compared to the standalone React template, you see some new and modified files for integration with ASP.NET Core:



- vite.config.js
- App.js (modified)
- App.test.js (modified)

5. Select an installed browser from the Debug toolbar, such as Chrome or Microsoft Edge.

   If the browser you want is not yet installed, install the browser first, and then select it.

Set the project properties

1. In Solution Explorer, right-click the **ReactWithASP.Server** project and choose **Properties**.

2. In the Properties page, open the **Debug** tab and select **Open debug launch profiles UI** option. Uncheck the **Launch Browser** option for the **https** profile or the profile named after the ASP.NET Core project, if present.

This value prevents opening the web page with the source weather data.

> ⓘ Note
>
> In Visual Studio, `launch.json` stores the startup settings associated with the **Start** button in the Debug toolbar. Currently, `launch.json` must be located under the `.vscode` folder.

3. Right-click the solution in Solution Explorer and select **Properties**. Verify that the Startup project settings are set to **Multiple projects**, and that the Action for both projects is set to **Start**.

Start the project

Press **F5** or select the **Start** button at the top of the window to start the app. Two command prompts appear:

- The ASP.NET Core API project running
- The Vite CLI showing a message such as `VITE v4.4.9 ready in 780 ms`

> ⓘ Note
>
> Check console output for messages. For example there might be a message to update Node.js.

The React app appears and is populated via the API. If you don't see the app, see Troubleshooting.

Publish the project

1. In Solution Explorer, right-click the **ReactWithASP.Server** project and select **Add** > **Project Reference**.

   Make sure the **reactwithasp.client** project is selected.

2. Choose **OK**.

3. Right-click the ASP.NET Core project again and select **Edit Project File**.

   This opens the `.csproj` file for the project.

4. In the `.csproj` file, make sure the project reference includes a `<ReferenceOutputAssembly>` element with the value set to `false`.

   This reference should look like the following.

   XML

   ```
    <ProjectReference
   Include="..\reactwithasp.client\reactwithasp.client.esproj">
      <ReferenceOutputAssembly>false</ReferenceOutputAssembly>
    </ProjectReference>
   ```

5. Right-click the ASP.NET Core project and choose **Reload Project** if that option is available.

6. In *Program.cs*, make sure the following code is present.

   C#

   ```
   app.UseDefaultFiles();
   app.UseStaticFiles();

   // Configure the HTTP request pipeline.
   if (app.Environment.IsDevelopment())
   {
      app.UseSwagger();
      app.UseSwaggerUI();
   }
   ```

7. To publish, right click the ASP.NET Core project, choose **Publish**, and select options to match your desired publish scenario, such as Azure, publish to a folder, etc.

   The publish process takes more time than it does for just an ASP.NET Core project, since the `npm run build` command gets invoked when publishing. The BuildCommand runs `npm run build` by default.

   If you publish to a folder, see ASP.NET Core directory structure for more information on the files added to the *publish* folder.

Troubleshooting

Proxy error

You may see the following error:

Windows Command Prompt

```
[HPM] Error occurred while trying to proxy request /weatherforecast from
localhost:4200 to https://localhost:7183 (ECONNREFUSED)
(https://nodejs.org/api/errors.html#errors_common_system_errors)
```

If you see this issue, most likely the frontend started before the backend.

- Once you see the backend command prompt up and running, just refresh the React app in the browser.
- Also, verify that the backend is configured to start before the front end. To verify, select the solution in Solution Explorer, choose **Properties** from the **Project menu**. Next, select **Configure Startup Projects** and make sure that the backend ASP.NET Core project is first in the list. If it's not first, select the project and use the Up arrow button to make it the first project in the launch list.

Verify ports

If the weather data doesn't load correctly, you may also need to verify that your ports are correct.

1. Make sure that the port numbers match. Go to the `launchSettings.json` file in the ASP.NET Core **ReactWithASP.Server** project (in the *Properties* folder). Get the port number from the `applicationUrl` property.

   If there are multiple `applicationUrl` properties, look for one using an `https` endpoint. It looks similar to `https://localhost:7183`.

2. Open the `vite.config.js` file for the React project. Update the `target` property to match the `applicationUrl` property in *launchSettings.json*. The updated value looks similar to the following:

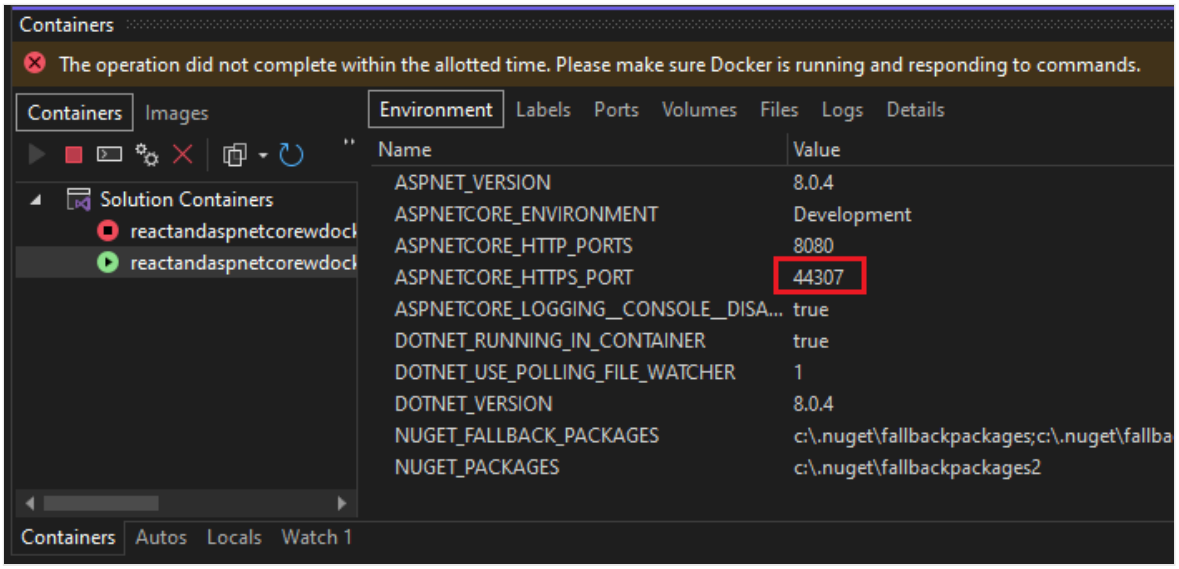
   JavaScript

   ```
   target: 'https://localhost:7183/',
   ```

Privacy error

You may see the following certificate error:

```
```



```
Your connection isn't private
```

Try deleting the React certificates from *%appdata%\local\asp.net\https* or *%appdata%\roaming\asp.net\https*, and then retry.

Docker

If you create the project with Docker support enabled, take the following steps:

1. After the app loads, get the Docker HTTPS port using the Containers window in Visual Studio. Check the **Environment** or **Ports** tab.

2. Open the `vite.config.js` file for the React project. Update the `target` variable to match the HTTPS port in the Containers window. For example, in the following code:

   JavaScript

   ```
   const target = env.ASPNETCORE_HTTPS_PORT ?
   `https://localhost:${env.ASPNETCORE_HTTPS_PORT}` :
      env.ASPNETCORE_URLS ? env.ASPNETCORE_URLS.split(';')[0] :
   'https://localhost:7143';
   ```

   change `https://localhost:7143` to the matching HTTPS port (in this example, `https://localhost:44307`).

3. Restart the app.

Next steps

For more information about SPA applications in ASP.NET Core, see the React section under Developing Single Page Apps. The linked article provides additional context for project files such as *aspnetcore-https.js*, although details of the implementation are different based on the template differences. For example, instead of a ClientApp folder, the React files are contained in a separate project.

For MSBuild information specific to the client project, see MSBuild properties for JSPS.

Tutorial: Create an ASP.NET Core app with Vue in Visual Studio

Article • 11/06/2024

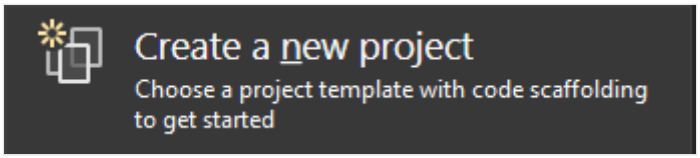
In this article, you learn how to build an ASP.NET Core project to act as an API backend and a Vue project to act as the UI.

Visual Studio includes ASP.NET Core Single Page Application (SPA) templates that support Angular, React, and Vue. The templates provide a built-in Client App folder in your ASP.NET Core projects that contains the base files and folders of each framework.

You can use the method described in this article to create ASP.NET Core Single Page Applications that:

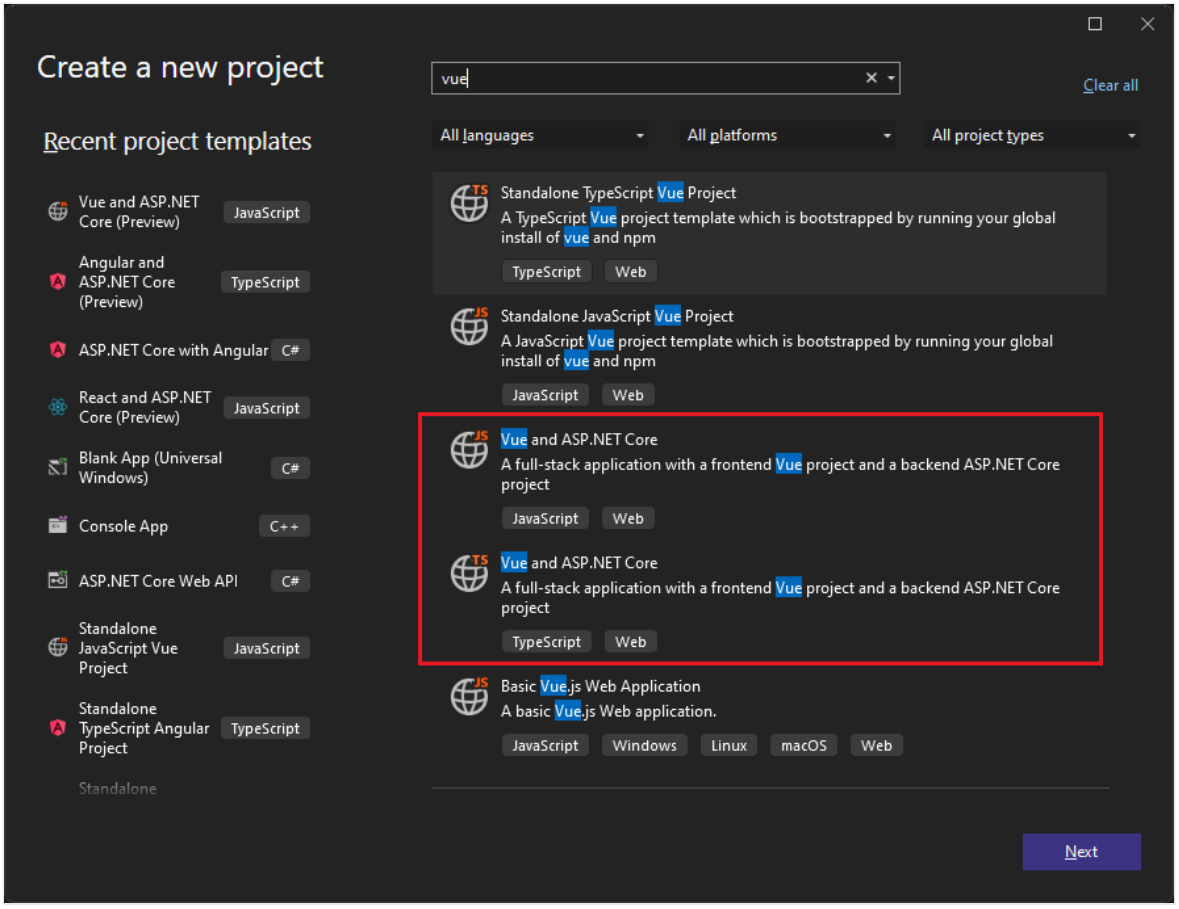
- Put the client app in a separate project, outside from the ASP.NET Core project
- Create the client project based on the framework CLI installed on your computer

> **Note**
>
> This article describes the project creation process using the updated template in Visual Studio 2022 version 17.11, which uses the Vite CLI.



Prerequisites

Make sure to install the following:

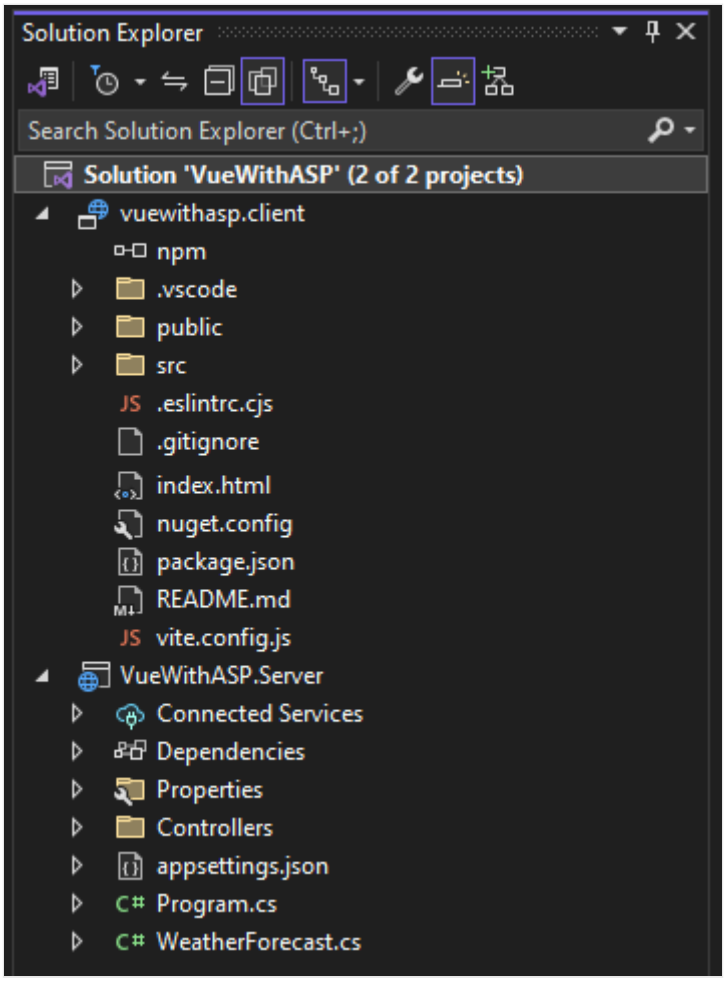


- Visual Studio 2022 version 17.11 or later with the **ASP.NET and web development** workload installed. Go to the Visual Studio downloads page to install it for free. If you need to install the workload and already have Visual Studio, go to **Tools** > **Get Tools and Features...**, which opens the Visual Studio Installer. Choose the **ASP.NET and web development** workload, then choose **Modify**.
- npm (https://www.npmjs.com/), which is included with Node.js.

Create the frontend app

1. In the Start window (choose **File** > **Start Window** to open), select **Create a new project**.

2. Search for Vue in the search bar at the top and then select **Vue and ASP.NET Core** with either JavaScript or TypeScript as the selected language.

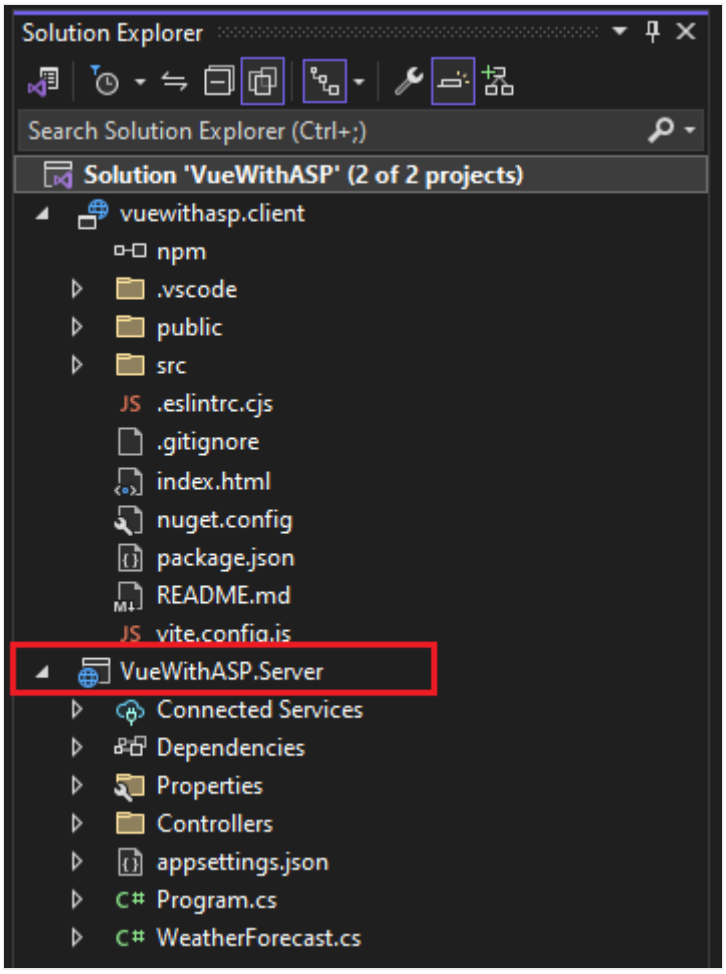


3. Name the project **VueWithASP** and then select **Next**.

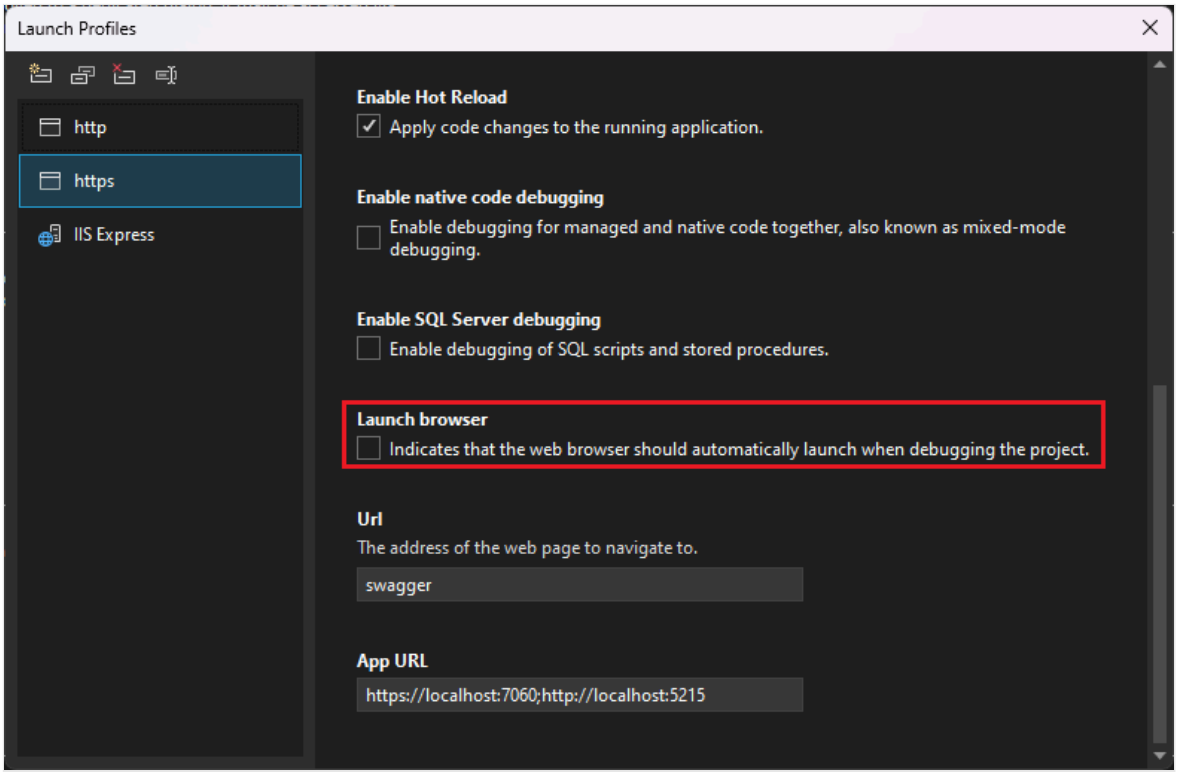
   In the Additional Information dialog, make sure that **Configure for HTTPS** is enabled. In most scenarios, leave the other settings at the default values.

4. Select **Create**.

   Solution Explorer shows the following project information:



Compared to the standalone Vue template, you see some new and modified files for integration with ASP.NET Core:



- vite.config.json (modified)
- HelloWorld.vue (modified)
- package.json (modified)

Set the project properties

1. In Solution Explorer, right-click the **VueWithASP.Server** and choose **Properties**.

2. In the Properties page, open the **Debug** tab and select **Open debug launch profiles UI** option. Uncheck the **Launch Browser** option for the **https** profile or the profile named after the ASP.NET Core project, if present.

This value prevents opening the web page with the source weather data.

> ⓘ Note
>
> In Visual Studio, `launch.json` stores the startup settings associated with the **Start** button in the Debug toolbar. Currently, `launch.json` must be located under the `.vscode` folder.

3. Right-click the solution in Solution Explorer and select **Properties**. Verify that the Startup project settings are set to **Multiple projects**, and that the Action for both projects is set to **Start**.

Start the project

Press **F5** or select the **Start** button at the top of the window to start the app. Two command prompts appear:

- The ASP.NET Core API project running
- The Vite CLI showing a message such as `VITE v4.4.9 ready in 780 ms`

> ⓘ Note
>
> Check console output for messages. For example there might be a message to update Node.js.

The Vue app appears and is populated via the API. If you don't see the app, see Troubleshooting.

Publish the project

Starting in Visual Studio 2022 version 17.3, you can publish the integrated solution using the Visual Studio Publish tool.

> ⓘ Note
>
> To use publish, create your JavaScript project using Visual Studio 2022 version 17.3 or later.

1. In Solution Explorer, right-click the **VueWithASP.Server** project and select **Add** > **Project Reference**.

Make sure the **vuewithasp.client** project is selected.

2. Choose **OK**.

3. Right-click the ASP.NET Core project again and select **Edit Project File**.

   This opens the `.csproj` file for the project.

4. In the `.csproj` file, make sure the project reference includes a `<ReferenceOutputAssembly>` element with the value set to `false`.

   This reference should look like the following.

   XML

   ```
    <ProjectReference
   Include="..\vuewithasp.client\vuewithasp.client.esproj">
      <ReferenceOutputAssembly>false</ReferenceOutputAssembly>
    </ProjectReference>
   ```

5. Right-click the ASP.NET Core project and choose **Reload Project** if that option is available.

6. In *Program.cs*, make sure the following code is present.

   C#

   ```
   app.UseDefaultFiles();
   app.UseStaticFiles();

   // Configure the HTTP request pipeline.
   if (app.Environment.IsDevelopment())
   {
      app.UseSwagger();
      app.UseSwaggerUI();
   }
   ```

7. To publish, right click the ASP.NET Core project, choose **Publish**, and select options to match your desired publish scenario, such as Azure, publish to a folder, etc.

   The publish process takes more time than it does for just an ASP.NET Core project, since the `npm run build` command gets invoked when publishing. The BuildCommand runs `npm run build` by default.

   If you publish to a folder, see ASP.NET Core directory structure for more information on the files added to the *publish* folder.

Troubleshooting

Proxy error

You may see the following error:

```
[HPM] Error occurred while trying to proxy request /weatherforecast from
localhost:4200 to https://localhost:5173 (ECONNREFUSED)
(https://nodejs.org/api/errors.html#errors_common_system_errors)
```

If you see this issue, most likely the frontend started before the backend.

- Once you see the backend command prompt up and running, just refresh the Vue app in the browser.
- Also, verify that the backend is configured to start before the front end. To verify, select the solution in Solution Explorer, choose **Properties** from the **Project menu**. Next, select **Configure Startup Projects** and make sure that the backend ASP.NET Core project is first in the list. If it's not first, select the project and use the Up arrow button to make it the first project in the launch list.

Otherwise, if the port is in use, try incrementing the port number by **1** in `launchSettings.json` and *vite.config.js*.

Privacy error

You may see the following certificate error:

```
Your connection isn't private
```

Try deleting the Vue certificates from *%appdata%\local\asp.net\https* or *%appdata%\roaming\asp.net\https*, and then retry.

Verify ports

If the weather data doesn't load correctly, you may also need to verify that your ports are correct.

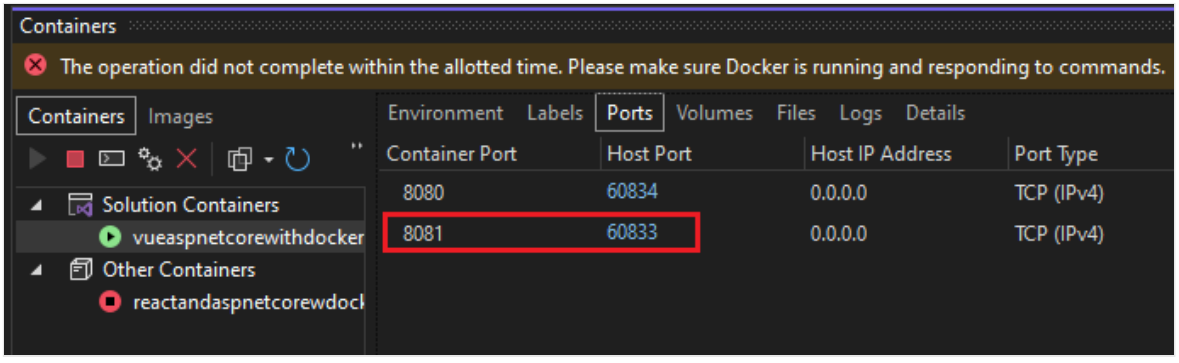
1. Make sure that the port numbers match. Go to the `launchSettings.json` file in your ASP.NET Core project (in the *Properties* folder). Get the port number from the `applicationUrl` property.

   If there are multiple `applicationUrl` properties, look for one using an `https` endpoint. It should look similar to `https://localhost:7142`.

2. Then, go to the `vite.config.js` file for your Vue project. Update the `target` property to match the `applicationUrl` property in *launchSettings.json*. When you update it, that value should look similar to this:

   JavaScript

   ```
   target: 'https://localhost:7142/',
   ```



Outdated version of Vue

If you see the console message **Could not find the file 'C:\Users\Me\source\repos\vueprojectname\package.json'** when you create the project, you may need to update your version of the Vite CLI. After you update the Vite CLI, you may also need to delete the `.vuerc` file in *C:\Users\[yourprofilename]*.

Docker

If you create the project with Docker support enabled, take the following steps:

1. After the app loads, get the Docker HTTPS port using the Containers window in Visual Studio. Check the **Environment** or **Ports** tab.

2. Open the `vite.config.js` file for the Vue project. Update the `target` variable to match the HTTPS port in the Containers window. For example, in the following code:

JavaScript

```
const target = env.ASPNETCORE_HTTPS_PORT ?
`https://localhost:${env.ASPNETCORE_HTTPS_PORT}` :
   env.ASPNETCORE_URLS ? env.ASPNETCORE_URLS.split(';')[0] :
'https://localhost:7163';
```

change `https://localhost:7163` to the matching HTTPS port (in this example, `https://localhost:60833`).

3. Restart the app.

If you are using a Docker configuration created in older versions of Visual Studio, the backend may start up using the Docker profile and not listen on the configured port 5173. To resolve:

Edit the Docker profile in the `launchSettings.json` by adding the following properties:

JSON

```
"httpPort": 5175,
"sslPort": 5173
```

Next steps

For more information about SPA applications in ASP.NET Core, see Developing Single Page Apps. The linked article provides additional context for project files such as *aspnetcore-https.js*, although details of the implementation are different due to differences between the project templates and the Vue.js framework vs. other frameworks. For example, instead of a ClientApp folder, the Vue files are contained in a separate project.

For MSBuild information specific to the client project, see MSBuild properties for JSPS.

JavaScript and TypeScript in Visual Studio

Article • 06/27/2024

Visual Studio 2022 provides rich support for JavaScript development, both using JavaScript directly, and also using the TypeScript programming language, which was developed to provide a more productive and enjoyable JavaScript development experience, especially when developing projects at scale. You can write JavaScript or TypeScript code in Visual Studio for many application types and services.

JavaScript language service

The JavaScript experience in Visual Studio 2022 is powered by the same engine that provides TypeScript support. This engine gives you better feature support, richness, and integration immediately out-of-the-box.

The option to restore to the legacy JavaScript language service is no longer available. Users have the new JavaScript language service out-of-the-box. The new language service is solely based on the TypeScript language service, which is powered by static analysis. This service enables us to provide you with better tooling, so your JavaScript code can benefit from richer IntelliSense based on type definitions. The new service is lightweight and consumes less memory than the legacy service, providing you with better performance as your code scales. We also improved performance of the language service to handle larger projects.

TypeScript support

By default, Visual Studio 2022 provides language support for JavaScript and TypeScript files to power IntelliSense without any specific project configuration.

For compiling TypeScript, Visual Studio gives you the flexibility to choose which version of TypeScript to use on a per-project basis.

In MSBuild compilation scenarios such as ASP.NET Core, the TypeScript NuGet package is the recommended method of adding TypeScript compilation support to your project. Visual Studio will give you the option to add this package the first time you add a TypeScript file to your project. This package is also available at any time through the NuGet package manager. When the NuGet package is used, the corresponding

language service version will be used for language support in your project. Note: The minimum supported version of this package is 3.6.

Projects configured for npm, such as Node.js projects, can specify their own version of the TypeScript language service by adding the TypeScript npm package. You can specify the version using the npm manager in supported projects. Note: The minimum supported version of this package is 2.1.

The TypeScript SDK has been deprecated in Visual Studio 2022. Existing projects that rely on the SDK should be upgraded to use the NuGet package. For projects that cannot be upgraded immediately, the SDK is still available on the Visual Studio Marketplace and as an optional component in the Visual Studio installer.

> **Tip**
>
> For projects developed in Visual Studio 2022, we encourage you to use the TypeScript NuGet or the TypeScript npm package for greater portability across different platforms and environments. For more information, see **Compile TypeScript code using NuGet** and **Compile TypeScript code using tsc**.

Project templates

Starting in Visual Studio 2022, there is a new JavaScript/TypeScript project type (.esproj), called the JavaScript Project System (JSPS), which allows you to create standalone Angular, React, and Vue projects in Visual Studio. These front-end projects are created using the framework CLI tools you have installed on your local machine, so the version of the template is up to you. To migrate from existing Node.js projects to the new project system, see Migrate Node.js projects. For MSBuild information for the new project type, see MSBuild properties for JSPS

Within these new projects, you can run JavaScript and TypeScript unit tests, easily add and connect ASP.NET Core API projects and download your npm modules using the npm manager. Check out some of the quickstarts and tutorials to get started. For more information, see Visual Studio tutorials | JavaScript and TypeScript.

> **Note**
>
> A simplified, updated template is available starting in Visual Studio 2022 version 17.5. Compared to the ASP.NET SPA templates available in Visual Studio, the *.esproj*

SPA templates for ASP.NET Core provide better npm dependency management, and better build and publish support.

Overview of Single Page Apps (SPAs) in ASP.NET Core

Article • 06/18/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

Visual Studio provides project templates for creating single-page apps (SPAs) based on JavaScript frameworks such as Angular, React, and Vue that have an ASP.NET Core backend. These templates:

- Create a Visual Studio solution with a frontend project and a backend project.
- Use the Visual Studio project type for JavaScript and TypeScript (*.esproj*) for the frontend.
- Use an ASP.NET Core project for the backend.

Projects created by using the Visual Studio templates can be run from the command line on Windows, Linux, and macOS. To run the app, use `dotnet run --launch-profile https` to run the server project. Running the server project automatically starts the frontend JavaScript development server. The `https` launch profile is currently required.

Visual Studio tutorials

To get started, follow one of the tutorials in the Visual Studio documentation:

- Create an ASP.NET Core app with Angular
- Create an ASP.NET Core app with React
- Create an ASP.NET Core app with Vue

For more information, see JavaScript and TypeScript in Visual Studio

ASP.NET Core SPA templates

Visual Studio includes templates for building ASP.NET Core apps with a JavaScript or TypeScript frontend. These templates are available in Visual Studio 2022 version 17.8 or later with the **ASP.NET and web development** workload installed.

The Visual Studio templates for building ASP.NET Core apps with a JavaScript or TypeScript frontend offer the following benefits:

- Clean project separation for the frontend and backend.
- Stay up-to-date with the latest frontend framework versions.
- Integrate with the latest frontend framework command-line tooling, such as Vite.
- Templates for both JavaScript & TypeScript (only TypeScript for Angular).
- Rich JavaScript and TypeScript code editing experience.
- Integrate JavaScript build tools with the .NET build.
- npm dependency management UI.
- Compatible with Visual Studio Code debugging and launch configuration.
- Run frontend unit tests in Test Explorer using JavaScript test frameworks.

Legacy ASP.NET Core SPA templates

Earlier versions of the .NET SDK included what are now legacy templates for building SPA apps with ASP.NET Core. For documentation on these older templates, see the ASP.NET Core 7.0 version of the SPA overview and the Angular and React articles.

Use the Angular project template with ASP.NET Core

Article • 09/29/2023

Visual Studio provides project templates for creating single-page apps (SPAs) based on JavaScript frameworks such as Angular, React, and Vue that have an ASP.NET Core backend. These templates:

- Create a Visual Studio solution with a frontend project and a backend project.
- Use the Visual Studio project type for JavaScript and TypeScript (*.esproj*) for the frontend.
- Use an ASP.NET Core project for the backend.

Projects created by using the Visual Studio templates can be run from the command line on Windows, Linux, and macOS. To run the app, use `dotnet run --launch-profile https` to run the server project. Running the server project automatically starts the frontend JavaScript development server. The `https` launch profile is currently required.

Visual Studio tutorial

To get started with an Angular project, follow the Create an ASP.NET Core app with Angular tutorial in the Visual Studio documentation.

For more information, see JavaScript and TypeScript in Visual Studio

ASP.NET Core SPA templates

Visual Studio includes templates for building ASP.NET Core apps with a JavaScript or TypeScript frontend. These templates are available in Visual Studio 2022 version 17.8 or later with the **ASP.NET and web development** workload installed.

The Visual Studio templates for building ASP.NET Core apps with a JavaScript or TypeScript frontend offer the following benefits:

Client-side library acquisition in ASP.NET Core with LibMan

Article • 06/18/2024

By Scott Addie

Library Manager (LibMan) is a lightweight, client-side library acquisition tool. LibMan downloads popular libraries and frameworks from the file system or from a content delivery network (CDN). The supported CDNs include CDNJS, jsDelivr, and unpkg. The selected library files are fetched and placed in the appropriate location within the ASP.NET Core project.

LibMan use cases

LibMan offers the following benefits:

- Only the library files you need are downloaded.
- Additional tooling, such as Node.js, npm, and WebPack, isn't necessary to acquire a subset of files in a library.
- Files can be placed in a specific location without resorting to build tasks or manual file copying.

LibMan isn't a package management system. If you're already using a package manager, such as npm or yarn, continue doing so. LibMan wasn't developed to replace those tools.

Additional resources

- Use LibMan with ASP.NET Core in Visual Studio
- Use the LibMan CLI with ASP.NET Core
- LibMan GitHub repository

Use the LibMan CLI with ASP.NET Core

Article • 06/18/2024

Library Manager (LibMan) is a lightweight, client-side library acquisition tool. LibMan downloads popular libraries and frameworks from the file system or from a content delivery network (CDN). The supported CDNs include CDNJS, jsDelivr, and unpkg. The selected library files are fetched and placed in the appropriate location within the ASP.NET Core project.

Prerequisites

- latest .NET SDK

Installation

The following command installs LibMan:

.NET CLI

```
dotnet tool install -g Microsoft.Web.LibraryManager.Cli
```

> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see dotnet tool install, --arch option. For more information, see GitHub issue dotnet/AspNetCore.Docs #29262.

A .NET Core Global Tool is installed from the Microsoft.Web.LibraryManager.Cli NuGet package.

Usage

Console

```
libman
```

To view the installed LibMan version:

Console

```
libman --version
```

To view the available CLI commands:

Console

```
libman --help
```

The preceding command displays output similar to the following:

Console

```
 1.0.163+g45474d37ed

Usage: libman [options] [command]

Options:
  --help|-h  Show help information
  --version  Show version information

Commands:
  cache      List or clean libman cache contents
  clean      Deletes all library files defined in libman.json from the
project
  init       Create a new libman.json
  install    Add a library definition to the libman.json file, and download
the
             library to the specified location
  restore    Downloads all files from provider and saves them to specified
             destination
  uninstall  Deletes all files for the specified library from their
specified
             destination, then removes the specified library definition from
             libman.json
  update     Updates the specified library

Use "libman [command] --help" for more information about a command.
```

The following sections outline the available CLI commands.

Initialize LibMan in the project

The `libman init` command creates a `libman.json` file if one doesn't exist. The file is created with the default item template content.

Synopsis

Console

```
libman init [-d|--default-destination] [-p|--default-provider] [--verbosity]
libman init [-h|--help]
```

Options

The following options are available for the `libman init` command:

- `-d|--default-destination <PATH>`

  A path relative to the current folder. Library files are installed in this location if no `destination` property is defined for a library in `libman.json`. The `<PATH>` value is written to the `defaultDestination` property of `libman.json`.

- `-p|--default-provider <PROVIDER>`

  The provider to use if no provider is defined for a given library. The `<PROVIDER>` value is written to the `defaultProvider` property of `libman.json`. Replace `<PROVIDER>` with one of the following values:
  - `cdnjs`
  - `filesystem`
  - `jsdelivr`
  - `unpkg`

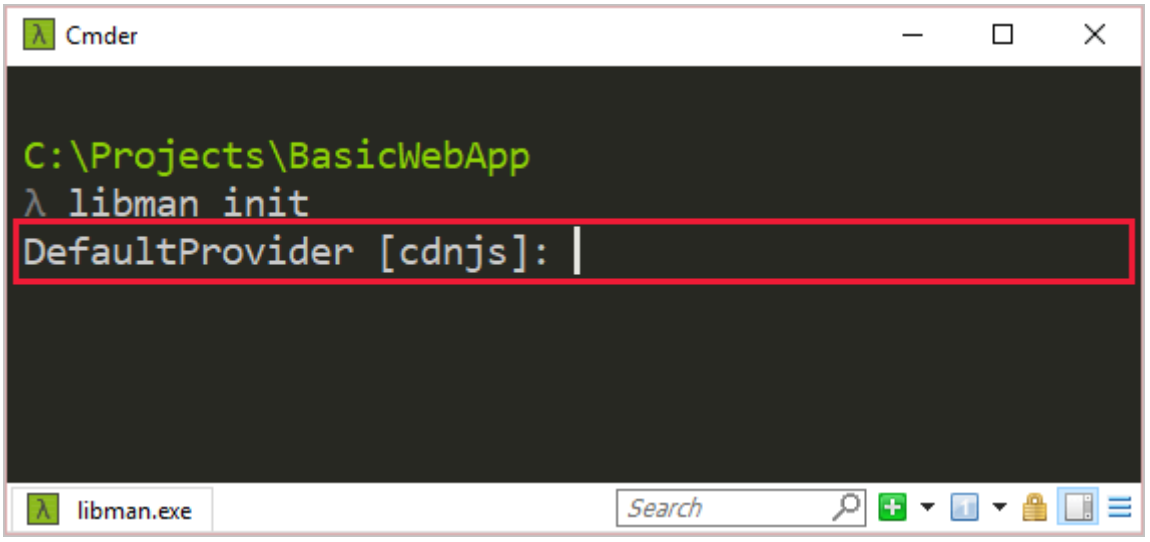
- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:
  - `quiet`
  - `normal`
  - `detailed`

Examples



To create a `libman.json` file in an ASP.NET Core project:

- Navigate to the project root.
- Run the following command:

```
Console

libman init
```

- Type the name of the default provider, or press `Enter` to use the default CDNJS provider. Valid values include:
  - `cdnjs`
  - `filesystem`
  - `jsdelivr`
  - `unpkg`

A `libman.json` file is added to the project root with the following content:

```
JSON

{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": []
}
```

Add library files

The `libman install` command downloads and installs library files into the project. A `libman.json` file is added if one doesn't exist. The `libman.json` file is modified to store configuration details for the library files.

Synopsis

Console

```
libman install <LIBRARY> [-d|--destination] [--files] [-p|--provider] [--
verbosity]
libman install [-h|--help]
```

Arguments

`LIBRARY`

The name of the library to install. This name may include version number notation (for example, `@1.2.0`).

Options

The following options are available for the `libman install` command:

- `-d|--destination <PATH>`

  The location to install the library. If not specified, the default location is used. If no `defaultDestination` property is specified in `libman.json`, this option is required.

  Note: There are limitations to the destination path. For example, when the package source has a full project structure and not just the distribution folder, you can't specify moving a folder. For more information, see Issue #407 and Issue #702

- `--files <FILE>`

  Specify the name of the file to install from the library. If not specified, all files from the library are installed. Provide one `--files` option per file to be installed. Relative paths are supported too. For example: `--files dist/browser/signalr.js`.

- `-p|--provider <PROVIDER>`

  The name of the provider to use for the library acquisition. Replace `<PROVIDER>` with one of the following values:
  - `cdnjs`
  - `filesystem`
  - `jsdelivr`
  - `unpkg`

If not specified, the `defaultProvider` property in `libman.json` is used. If no `defaultProvider` property is specified in `libman.json`, this option is required.

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:
  - `quiet`
  - `normal`
  - `detailed`

Examples

Consider the following `libman.json` file:

JSON

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": []
}
```

To install the jQuery version 3.2.1 `jquery.min.js` file to the *wwwroot/scripts/jquery* folder using the CDNJS provider:

Console

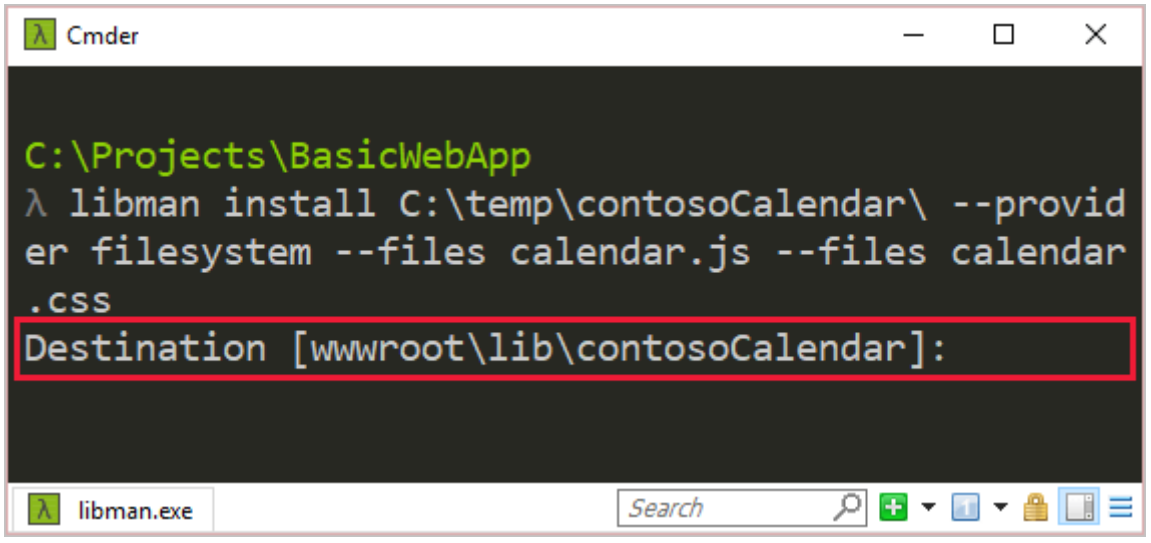
```
libman install jquery@3.2.1 --provider cdnjs --destination
wwwroot/scripts/jquery --files jquery.min.js
```

The `libman.json` file resembles the following:

JSON

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.2.1",
      "destination": "wwwroot/scripts/jquery",
      "files": [
```

```
        "jquery.min.js"
      ]
    }
  ]
}
```



To install the `calendar.js` and `calendar.css` files from *C:\temp\contosoCalendar* using the file system provider:

Console

```
libman install C:\temp\contosoCalendar\ --provider filesystem --files
calendar.js --files calendar.css
```

The following prompt appears for two reasons:

- The `libman.json` file doesn't contain a `defaultDestination` property.
- The `libman install` command doesn't contain the `-d|--destination` option.

After accepting the default destination, the `libman.json` file resembles the following:

JSON

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.2.1",
      "destination": "wwwroot/scripts/jquery",
      "files": [
        "jquery.min.js"
      ]
    },
    {
```

```
      "library": "C:\\temp\\contosoCalendar\\",
      "provider": "filesystem",
      "destination": "wwwroot/lib/contosoCalendar",
      "files": [
        "calendar.js",
        "calendar.css"
      ]
    }
  ]
}
```

Restore library files

The `libman restore` command installs library files defined in `libman.json`. The following rules apply:

- If no `libman.json` file exists in the project root, an error is returned.
- If a library specifies a provider, the `defaultProvider` property in `libman.json` is ignored.
- If a library specifies a destination, the `defaultDestination` property in `libman.json` is ignored.

Synopsis

Console

```
libman restore [--verbosity]
libman restore [-h|--help]
```

Options

The following options are available for the `libman restore` command:

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:
  - `quiet`
  - `normal`
  - `detailed`

Examples

To restore the library files defined in `libman.json`:

```
Console

libman restore
```

Delete library files

The `libman clean` command deletes library files previously restored via LibMan. Folders that become empty after this operation are deleted. The library files' associated configurations in the `libraries` property of `libman.json` aren't removed.

Synopsis

```
Console

libman clean [--verbosity]
libman clean [-h|--help]
```

Options

The following options are available for the `libman clean` command:

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:
  - `quiet`
  - `normal`
  - `detailed`

Examples

To delete library files installed via LibMan:

```
Console
```

```
libman clean
```

Uninstall library files

The `libman uninstall` command:

- Deletes all files associated with the specified library from the destination in `libman.json`.
- Removes the associated library configuration from `libman.json`.

An error occurs when:

- No `libman.json` file exists in the project root.
- The specified library doesn't exist.

If more than one library with the same name is installed, you're prompted to choose one.

Synopsis

Console

```
libman uninstall <LIBRARY> [--verbosity]
libman uninstall [-h|--help]
```

Arguments

`LIBRARY`

The name of the library to uninstall. This name may include version number notation (for example, `@1.2.0`).

Options

The following options are available for the `libman uninstall` command:

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:

- `quiet`
- `normal`
- `detailed`

Examples

Consider the following `libman.json` file:

JSON

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.3.1",
      "files": [
        "jquery.min.js",
        "jquery.js",
        "jquery.min.map"
      ],
      "destination": "wwwroot/lib/jquery/"
    },
    {
      "provider": "unpkg",
      "library": "bootstrap@4.1.3",
      "destination": "wwwroot/lib/bootstrap/"
    },
    {
      "provider": "filesystem",
      "library": "C:\\temp\\lodash\\",
      "files": [
        "lodash.js",
        "lodash.min.js"
      ],
      "destination": "wwwroot/lib/lodash/"
    }
  ]
}
```

- To uninstall jQuery, either of the following commands succeed:

  Console

  ```
  libman uninstall jquery
  ```

  Console

```
libman uninstall jquery@3.3.1
```

- To uninstall the Lodash files installed via the `filesystem` provider:

```
Console

libman uninstall C:\temp\lodash\
```

Update library version

The `libman update` command updates a library installed via LibMan to the specified version.

An error occurs when:

- No `libman.json` file exists in the project root.
- The specified library doesn't exist.

If more than one library with the same name is installed, you're prompted to choose one.

Synopsis

```
Console

libman update <LIBRARY> [-pre] [--to] [--verbosity]
libman update [-h|--help]
```

Arguments

`LIBRARY`

The name of the library to update.

Options

The following options are available for the `libman update` command:

- `-pre`

  Obtain the latest prerelease version of the library.

- `--to <VERSION>`

  Obtain a specific version of the library.

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:
  - `quiet`
  - `normal`
  - `detailed`

Examples

- To update jQuery to the latest version:

  ```
  Console
  libman update jquery
  ```

- To update jQuery to version 3.3.1:

  ```
  Console
  libman update jquery --to 3.3.1
  ```

- To update jQuery to the latest prerelease version:

  ```
  Console
  libman update jquery -pre
  ```

Manage library cache

The `libman cache` command manages the LibMan library cache. The `filesystem` provider doesn't use the library cache.

Synopsis

```
```

Console

```
libman cache clean [<PROVIDER>] [--verbosity]
libman cache list [--files] [--libraries] [--verbosity]
libman cache [-h|--help]
```

Arguments

`PROVIDER`

Only used with the `clean` command. Specifies the provider cache to clean. Valid values include:

- `cdnjs`
- `filesystem`
- `jsdelivr`
- `unpkg`

Options

The following options are available for the `libman cache` command:

- `--files`

  List the names of files that are cached.

- `--libraries`

  List the names of libraries that are cached.

- `-h|--help`

  Show help information.

- `--verbosity <LEVEL>`

  Set the verbosity of the output. Replace `<LEVEL>` with one of the following values:
  - `quiet`
  - `normal`
  - `detailed`

Examples

- To view the names of cached libraries per provider, use one of the following commands:

  Console

  ```
  libman cache list
  ```

  Console

  ```
  libman cache list --libraries
  ```

  Output similar to the following is displayed:

  Console

  ```
  Cache contents:
  ---------------
  unpkg:
      knockout
      react
      vue
  cdnjs:
      font-awesome
      jquery
      knockout
      lodash.js
      react
  ```

- To view the names of cached library files per provider:

  Console

  ```
  libman cache list --files
  ```

  Output similar to the following is displayed:

  Console

  ```
  Cache contents:
  ---------------
  unpkg:
      knockout:
          <list omitted for brevity>
      react:
          <list omitted for brevity>
      vue:
          <list omitted for brevity>
  cdnjs:
  ```

```
    font-awesome
        metadata.json
    jquery
        metadata.json
        3.2.1\core.js
        3.2.1\jquery.js
        3.2.1\jquery.min.js
        3.2.1\jquery.min.map
        3.2.1\jquery.slim.js
        3.2.1\jquery.slim.min.js
        3.2.1\jquery.slim.min.map
        3.3.1\core.js
        3.3.1\jquery.js
        3.3.1\jquery.min.js
        3.3.1\jquery.min.map
        3.3.1\jquery.slim.js
        3.3.1\jquery.slim.min.js
        3.3.1\jquery.slim.min.map
    knockout
        metadata.json
        3.4.2\knockout-debug.js
        3.4.2\knockout-min.js
    lodash.js
        metadata.json
        4.17.10\lodash.js
        4.17.10\lodash.min.js
    react
        metadata.json
```

Notice the preceding output shows that jQuery versions 3.2.1 and 3.3.1 are cached under the CDNJS provider.

- To empty the library cache for the CDNJS provider:

Console

```
libman cache clean cdnjs
```

After emptying the CDNJS provider cache, the `libman cache list` command displays the following:

Console

```
Cache contents:
---------------
unpkg:
    knockout
    react
    vue
```

```
cdnjs:
    (empty)
```

- To empty the cache for all supported providers:

  Console

  ```
  libman cache clean
  ```

  After emptying all provider caches, the `libman cache list` command displays the following:

  Console

  ```
  Cache contents:
  ---------------
  unpkg:
      (empty)
  cdnjs:
      (empty)
  ```

Use LibMan with ASP.NET Core in Visual Studio

Article • 06/18/2024

By Scott Addie

Visual Studio has built-in support for LibMan in ASP.NET Core projects, including:

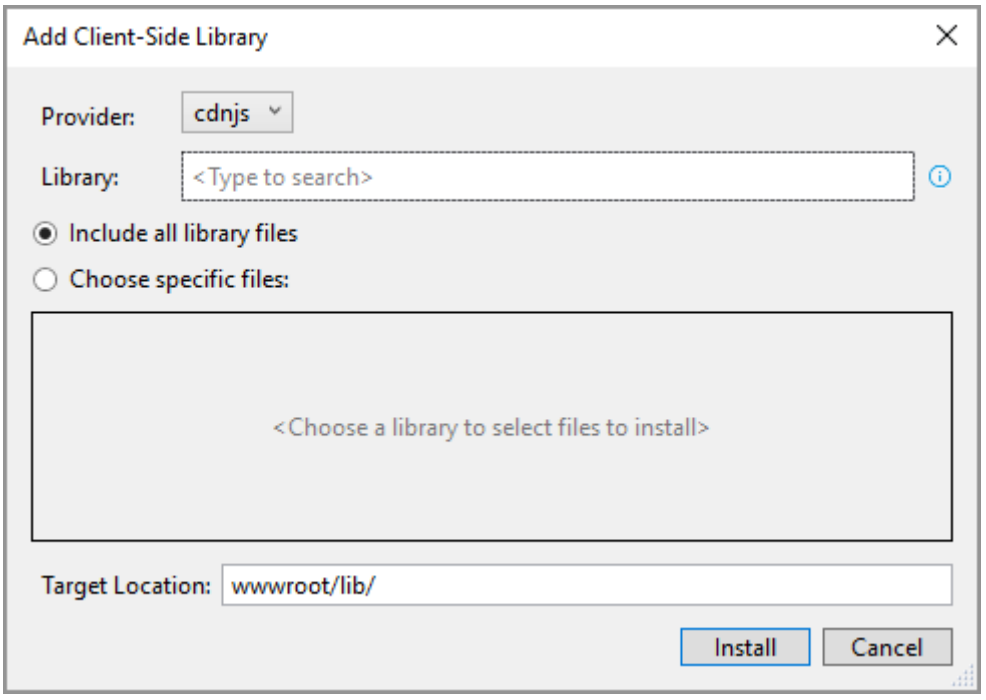
- Support for configuring and running LibMan restore operations on build.
- Menu items for triggering LibMan restore and clean operations.
- Search dialog for finding libraries and adding the files to a project.
- Editing support for `libman.json`—the LibMan manifest file.

View or download sample code (how to download)

Prerequisites

- Visual Studio 2019 with the **ASP.NET and web development** workload

Add library files



Library files can be added to an ASP.NET Core project in two different ways:

1. Use the Add Client-Side Library dialog
2. Manually configure LibMan manifest file entries

Use the Add Client-Side Library dialog

Follow these steps to install a client-side library:

- In **Solution Explorer**, right-click the project folder in which the files should be added. Choose **Add** > **Client-Side Library**. The **Add Client-Side Library** dialog appears:

- Select the library provider from the **Provider** drop down. CDNJS is the default provider.
- Type the library name to fetch in the **Library** text box. IntelliSense provides a list of libraries beginning with the provided text.
- Select the library from the IntelliSense list. Notice the library name is suffixed with the `@` symbol and the latest stable version known to the selected provider.
- Decide which files to include:
  - Select the **Include all library files** radio button to include all of the library's files.
  - Select the **Choose specific files** radio button to include a subset of the library's files. When the radio button is selected, the file selector tree is enabled. Check the boxes to the left of the file names to download.
- Specify the project folder for storing the files in the **Target Location** text box. As a recommendation, store each library in a separate folder.

  The suggested **Target Location** folder is based on the location from which the dialog launched:
  - If launched from the project root:
    - *wwwroot/lib* is used if *wwwroot* exists.
    - *lib* is used if *wwwroot* doesn't exist.
  - If launched from a project folder, the corresponding folder name is used.

  The folder suggestion is suffixed with the library name. The following table illustrates folder suggestions when installing jQuery in a Razor Pages project.

Expand table

Launch location	Suggested folder
project root (if *wwwroot* exists)	*wwwroot/lib/jquery/*
project root (if *wwwroot* doesn't exist)	*lib/jquery/*
Pages folder in project	*Pages/jquery/*

- Click the **Install** button to download the files, per the configuration in `libman.json`.
- Review the **Library Manager** feed of the **Output** window for installation details. For example:

Console

```
Restore operation started...
Restoring libraries for project LibManSample
Restoring library jquery@3.3.1... (LibManSample)
wwwroot/lib/jquery/jquery.min.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.min.map written to destination (LibManSample)
Restore operation completed
1 libraries restored in 2.32 seconds
```

Manually configure LibMan manifest file entries

All LibMan operations in Visual Studio are based on the content of the project root's LibMan manifest (`libman.json`). You can manually edit `libman.json` to configure library files for the project. Visual Studio restores all library files once `libman.json` is saved.

To open `libman.json` for editing, the following options exist:

- Double-click the `libman.json` file in **Solution Explorer**.
- Right-click the project in **Solution Explorer** and select **Manage Client-Side Libraries**. †
- Select **Manage Client-Side Libraries** from the Visual Studio **Project** menu. †

† If the `libman.json` file doesn't already exist in the project root, it will be created with the default item template content.

Visual Studio offers rich JSON editing support such as colorization, formatting, IntelliSense, and schema validation. The LibMan manifest's JSON schema is found at https://json.schemastore.org/libman.

With the following manifest file, LibMan retrieves files per the configuration defined in the `libraries` property. An explanation of the object literals defined within `libraries` follows:

- A subset of jQuery version 3.3.1 is retrieved from the CDNJS provider. The subset is defined in the `files` property—`jquery.min.js`, `jquery.js`, and *jquery.min.map*. The files are placed in the project's *wwwroot/lib/jquery* folder.
- The entirety of Bootstrap version 4.1.3 is retrieved and placed in a *wwwroot/lib/bootstrap* folder. The object literal's `provider` property overrides the `defaultProvider` property value. LibMan retrieves the Bootstrap files from the unpkg provider.
- A subset of Lodash was approved by a governing body within the organization. The `lodash.js` and `lodash.min.js` files are retrieved from the local file system at *C:\temp\lodash*. The files are copied to the project's *wwwroot/lib/lodash* folder.

JSON

```
{
  "version": "1.0",
  "defaultProvider": "cdnjs",
  "libraries": [
    {
      "library": "jquery@3.3.1",
      "files": [
        "jquery.min.js",
        "jquery.js",
        "jquery.min.map"
      ],
      "destination": "wwwroot/lib/jquery/"
    },
    {
      "provider": "unpkg",
      "library": "bootstrap@4.1.3",
      "destination": "wwwroot/lib/bootstrap/"
    },
    {
      "provider": "filesystem",
      "library": "C:\\temp\\lodash\\",
      "files": [
        "lodash.js",
        "lodash.min.js"
      ],
      "destination": "wwwroot/lib/lodash/"
    }
  ]
}
```

> **Note**
>
> LibMan only supports one version of each library from each provider. The `libman.json` file fails schema validation if it contains two libraries with the same library name for a given provider.

Restore library files

To restore library files from within Visual Studio, there must be a valid `libman.json` file in the project root. Restored files are placed in the project at the location specified for each library.

Library files can be restored in an ASP.NET Core project in two ways:

1. Restore files during build
2. Restore files manually

Restore files during build

LibMan can restore the defined library files as part of the build process. By default, the *restore-on-build* behavior is disabled.

To enable and test the restore-on-build behavior:

- Right-click `libman.json` in **Solution Explorer** and select **Enable Restore Client-Side Libraries on Build** from the context menu.
- Click the **Yes** button when prompted to install a NuGet package. The Microsoft.Web.LibraryManager.Build NuGet package is added to the project:

  XML

  ```
  <PackageReference Include="Microsoft.Web.LibraryManager.Build"
  Version="1.0.113" />
  ```

- Build the project to confirm LibMan file restoration occurs. The `Microsoft.Web.LibraryManager.Build` package injects an MSBuild target that runs LibMan during the project's build operation.
- Review the **Build** feed of the **Output** window for a LibMan activity log:

  Console

```
1>------ Build started: Project: LibManSample, Configuration: Debug Any
CPU ------
1>
1>Restore operation started...
1>Restoring library jquery@3.3.1...
1>Restoring library bootstrap@4.1.3...
1>
1>2 libraries restored in 10.66 seconds
1>LibManSample ->
C:\LibManSample\bin\Debug\netcoreapp2.1\LibManSample.dll
========== Build: 1 succeeded, 0 failed, 0 up-to-date, 0 skipped
==========
```

When the restore-on-build behavior is enabled, the `libman.json` context menu displays a **Disable Restore Client-Side Libraries on Build** option. Selecting this option removes the `Microsoft.Web.LibraryManager.Build` package reference from the project file. Consequently, the client-side libraries are no longer restored on each build.

Regardless of the restore-on-build setting, you can manually restore at any time from the `libman.json` context menu. For more information, see Restore files manually.

Restore files manually

To manually restore library files:

- For all projects in the solution:
  - Right-click the solution name in **Solution Explorer**.
  - Select the **Restore Client-Side Libraries** option.
- For a specific project:
  - Right-click the `libman.json` file in **Solution Explorer**.
  - Select the **Restore Client-Side Libraries** option.

While the restore operation is running:

- The Task Status Center (TSC) icon on the Visual Studio status bar will be animated and will read *Restore operation started*. Clicking the icon opens a tooltip listing the known background tasks.
- Messages will be sent to the status bar and the **Library Manager** feed of the **Output** window. For example:

Console

```
Restore operation started...
Restoring libraries for project LibManSample
```

```
Restoring library jquery@3.3.1... (LibManSample)
wwwroot/lib/jquery/jquery.min.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.js written to destination (LibManSample)
wwwroot/lib/jquery/jquery.min.map written to destination (LibManSample)
Restore operation completed
1 libraries restored in 2.32 seconds
```

Delete library files

To perform the *clean* operation, which deletes library files previously restored in Visual Studio:

- Right-click the `libman.json` file in **Solution Explorer**.
- Select the **Clean Client-Side Libraries** option.

To prevent unintentional removal of non-library files, the clean operation doesn't delete whole directories. It only removes files that were included in the previous restore.

While the clean operation is running:

- The TSC icon on the Visual Studio status bar will be animated and will read *Client libraries operation started*. Clicking the icon opens a tooltip listing the known background tasks.
- Messages are sent to the status bar and the **Library Manager** feed of the **Output** window. For example:

Console

```
Clean libraries operation started...
Clean libraries operation completed
2 libraries were successfully deleted in 1.91 secs
```

The clean operation only deletes files from the project. Library files stay in the cache for faster retrieval on future restore operations. To manage library files stored in the local machine's cache, use the LibMan CLI.

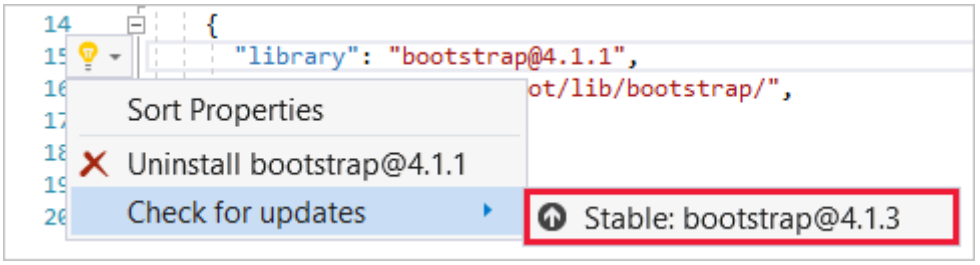
Uninstall library files

To uninstall library files:

- Open `libman.json`.
- Position the caret inside the corresponding `libraries` object literal.

- Click the light bulb icon that appears in the left margin, and select **Uninstall <library_name>@<library_version>**:

Alternatively, you can manually edit and save the LibMan manifest (`libman.json`). The restore operation runs when the file is saved. Library files that are no longer defined in `libman.json` are removed from the project.



Update library version

To check for an updated library version:

- Open `libman.json`.
- Position the caret inside the corresponding `libraries` object literal.
- Click the light bulb icon that appears in the left margin. Hover over **Check for updates**.

LibMan checks for a library version newer than the version installed. The following outcomes can occur:

- A **No updates found** message is displayed if the latest version is already installed.
- The latest stable version is displayed if not already installed.

- If a pre-release newer than the installed version is available, the pre-release is displayed.

To downgrade to an older library version, manually edit the `libman.json` file. When the file is saved, the LibMan restore operation:

- Removes redundant files from the previous version.
- Adds new and updated files from the new version.

Additional resources

- Use the LibMan CLI with ASP.NET Core
- LibMan GitHub repository

JavaScript `[JSImport]`/`[JSExport]` interop in .NET WebAssembly

Article • 08/22/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

By Aaron Shumaker

This article explains how to interact with JavaScript (JS) in client-side WebAssembly using JS `[JSImport]`/`[JSExport]` interop (System.Runtime.InteropServices.JavaScript API).

`[JSImport]`/`[JSExport]` interop is applicable when running a .NET WebAssembly module in a JS host in the following scenarios:

- JavaScript `[JSImport]`/`[JSExport]` interop with a WebAssembly Browser App project.
- JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.
- Other .NET WebAssembly platforms that support `[JSImport]`/`[JSExport]` interop.

Prerequisites

.NET SDK (latest version)

Any of the following project types:

- A WebAssembly Browser App project created according to JavaScript `[JSImport]`/`[JSExport]` interop with a WebAssembly Browser App project.
- A Blazor client-side project created according to JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.
- A project created for a commercial or open-source platform that supports `[JSImport]`/`[JSExport]` interop (System.Runtime.InteropServices.JavaScript API).

Sample app

View or download sample code (how to download): Select an 8.0 or later version folder that matches the version of .NET that you're adopting. Within the version folder, access the sample named `WASMBrowserAppImportExportInterop`.

JS interop using `[JSImport]` / `[JSExport]` attributes

The `[JSImport]` attribute is applied to a .NET method to indicate that a corresponding JS method should be called when the .NET method is called. This allows .NET developers to define "imports" that enable .NET code to call into JS. Additionally, an Action can be passed as a parameter, and JS can invoke the action to support a callback or event subscription pattern.

The `[JSExport]` attribute is applied to a .NET method to expose it to JS code. This allows JS code to initiate calls to the .NET method.

Importing JS methods

The following example imports a standard built-in JS method (`console.log`) into C#. `[JSImport]` is limited to importing methods of globally-accessible objects. For example, `log` is a method defined on the `console` object, which is defined on the globally-accessible object `globalThis`. The `console.log` method is mapped to a C# proxy method, `ConsoleLog`, which accepts a string for the log message:

C#

```
public partial class GlobalInterop
{
    [JSImport("globalThis.console.log")]
    public static partial void ConsoleLog(string text);
}
```

In `Program.Main`, `ConsoleLog` is called with the message to log:

C#

```
GlobalInterop.ConsoleLog("Hello World!");
```

The output appears in the browser's console.

The following demonstrates importing a method declared in JS.

The following custom JS method (`globalThis.callAlert`) spawns an alert dialog (window.alert) with the message passed in `text`:

JavaScript

```
globalThis.callAlert = function (text) {
  globalThis.window.alert(text);
}
```

The `globalThis.callAlert` method is mapped to a C# proxy method (`CallAlert`), which accepts a string for the message:

C#

```
using System.Runtime.InteropServices.JavaScript;

public partial class GlobalInterop
{
    [JSImport("globalThis.callAlert")]
    public static partial void CallAlert(string text);
}
```

In `Program.Main`, `CallAlert` is called, passing the text for the alert dialog message:

C#

```
GlobalInterop.CallAlert("Hello World");
```

The C# class declaring the `[JSImport]` method doesn't have an implementation. At compile time, a source-generated partial class contains the .NET code that implements the marshalling of the call and types to invoke the corresponding JS method. In Visual Studio, using the **Go To Definition** or **Go To Implementation** options respectively navigates to either the source-generated partial class or the developer-defined partial class.

In the preceding example, the intermediate `globalThis.callAlert` JS declaration is used to wrap existing JS code. This article informally refers to the intermediate JS declaration as a *JS shim*. JS shims fill the gap between the .NET implementation and existing JS capabilities/libraries. In many cases, such as the preceding trivial example, the JS shim isn't necessary, and methods could be imported directly, as demonstrated in the earlier `ConsoleLog` example. As this article demonstrates in the upcoming sections, a JS shim can:

- Encapsulate additional logic.
- Manually map types.
- Reduce the number of objects or calls crossing the interop boundary.
- Manually map static calls to instance methods.

Loading JavaScript declarations

JS declarations which are intended to be imported with `[JSImport]` are typically loaded in the context of the same page or JS host that loaded .NET WebAssembly. This can be accomplished with:

- A `<script>...</script>` block declaring inline JS.
- A script source (`src`) declaration (`<script src="./some.js"></script>`) that loads an external JS file (`.js`).
- A JS ES6 module (`<script type='module' src="./moduleName.js"></script>`).
- A JS ES6 module loaded using JSHost.ImportAsync from .NET WebAssembly.

Examples in this article use JSHost.ImportAsync. When calling ImportAsync, client-side .NET WebAssembly requests the file using the `moduleUrl` parameter, and thus it expects the file to be accessible as a static web asset, much the same way as a `<script>` tag retrieves a file with a `src` URL. For example, the following C# code within a WebAssembly Browser App project maintains the JS file (`.js`) at the path `/wwwroot/scripts/ExampleShim.js`:

C#

```
await JSHost.ImportAsync("ExampleShim", "/scripts/ExampleShim.js");
```

Depending on the platform that's loading WebAssembly, a dot-prefixed URL, such as `./scripts/`, might refer to an incorrect subdirectory, such as `/_framework/scripts/`, because the WebAssembly package is initialized by framework scripts under `/_framework/`. In that case, prefixing the URL with `../scripts/` refers to the correct path. Prefixing with `/scripts/` works if the site is hosted at the root of the domain. A typical approach involves configuring the correct base path for the given environment with an HTML `<base>` tag and using the `/scripts/` prefix to refer to the path relative to the base path. Tilde notation `~/` prefixes aren't supported by JSHost.ImportAsync.

> **ⓘ Important**

If JS is loaded from a JavaScript module, then `[JSImport]` attributes must include the module name as the second parameter. For example, `[JSImport("globalThis.callAlert", "ExampleShim")]` indicates the imported method was declared in a JavaScript module named "`ExampleShim`."

Type mappings

Parameters and return types in the .NET method signature are automatically converted to or from appropriate JS types at runtime if a unique mapping is supported. This may result in values converted by value or references wrapped in a proxy type. This process is known as *type marshalling*. Use JSMarshalAsAttribute<T> to control how the imported method parameters and return types are marshalled.

Some types don't have a default type mapping. For example, a `long` can be marshalled as System.Runtime.InteropServices.JavaScript.JSType.Number or System.Runtime.InteropServices.JavaScript.JSType.BigInt, so the JSMarshalAsAttribute<T> is required to avoid a compile-time error.

The following type mapping scenarios are supported:

- Passing Action or Func<TResult> as parameters, which are are marshalled as callable JS methods. This allows .NET code to invoke listeners in response to JS callbacks or events.
- Passing JS references and .NET managed object references in either direction, which as marshaled as proxy objects and kept alive across the interop boundary until the proxy is garbage collected.
- Marshalling asynchronous JS methods or a JS Promise with a Task result, and vice versa.

Most of the marshalled types work in both directions, as parameters and as return values, on both imported and exported methods.

The following table indicates the supported type mappings.

Expand table

.NET	JavaScript	`Nullable`	`Task` ➔ `Promise`	`JSMarshalAs` optional	`Array` of
`Boolean`	`Boolean`	✅	✅	✅	
`Byte`	`Number`	✅	✅	✅	✅

.NET	JavaScript	`Nullable`	`Task` ➔ `Promise`	`JSMarshalAs` optional	`Array of`
`Char`	`String`	✅	✅	✅	
`Int16`	`Number`	✅	✅	✅	
`Int32`	`Number`	✅	✅	✅	✅
`Int64`	`Number`	✅	✅		
`Int64`	`BigInt`	✅	✅		
`Single`	`Number`	✅	✅	✅	
`Double`	`Number`	✅	✅	✅	✅
`IntPtr`	`Number`	✅	✅	✅	
`DateTime`	`Date`	✅	✅		
`DateTimeOffset`	`Date`	✅	✅		
`Exception`	`Error`		✅	✅	
`JSObject`	`Object`		✅	✅	✅
`String`	`String`		✅	✅	✅
`Object`	`Any`		✅		✅
`Span<Byte>`	`MemoryView`				
`Span<Int32>`	`MemoryView`				
`Span<Double>`	`MemoryView`				
`ArraySegment<Byte>`	`MemoryView`				
`ArraySegment<Int32>`	`MemoryView`				
`ArraySegment<Double>`	`MemoryView`				
`Task`	`Promise`			✅	
`Action`	`Function`				
`Action<T1>`	`Function`				
`Action<T1, T2>`	`Function`				
`Action<T1, T2, T3>`	`Function`				

.NET	JavaScript	`Nullable`	`Task` → `Promise`	`JSMarshalAs` optional	`Array of`
`Func<TResult>`	`Function`				
`Func<T1, TResult>`	`Function`				
`Func<T1, T2, TResult>`	`Function`				
`Func<T1, T2, T3, TResult>`	`Function`				

The following conditions apply to type mapping and marshalled values:

- The `Array of` column indicates if the .NET type can be marshalled as a JS Array. Example: C# `int[]` (`Int32`) mapped to JS `Array` of `Number`s.
- When passing a JS value to C# with a value of the wrong type, the framework throws an exception in most cases. The framework doesn't perform compile-time type checking in JS.
- `JSObject`, `Exception`, `Task` and `ArraySegment` create `GCHandle` and a proxy. You can trigger disposal in developer code or allow .NET garbage collection (GC) to dispose of the objects later. These types carry significant performance overhead.
- `Array`: Marshaling an array creates a copy of the array in JS or .NET.
- `MemoryView`
  - `MemoryView` is a JS class for the .NET WebAssembly runtime to marshal `Span` and `ArraySegment`.
  - Unlike marshaling an array, marshaling a `Span` or `ArraySegment` doesn't create a copy of the underlying memory.
  - `MemoryView` can only be properly instantiated by the .NET WebAssembly runtime. Therefore, it isn't possible to import a JS method as a .NET method that has a parameter of `Span` or `ArraySegment`.
  - `MemoryView` created for a `Span` is only valid for the duration of the interop call. As `Span` is allocated on the call stack, which doesn't persist after the interop call, it isn't possible to export a .NET method that returns a `Span`.
  - `MemoryView` created for an `ArraySegment` survives after the interop call and is useful for sharing a buffer. Calling `dispose()` on a `MemoryView` created for an `ArraySegment` disposes the proxy and unpins the underlying .NET array. We recommend calling `dispose()` in a `try-finally` block for `MemoryView`.

Some combinations of type mappings that require nested generic types in JSMarshalAs aren't currently supported. For example, attempting to materialize an array from a Promise such as `[return: JSMarshalAs<JSType.Promise<JSType.Array<JSType.Number>>>`

`()]` generates a compile-time error. An appropriate workaround varies depending on the scenario, but this specific scenario is further explored in the Type mapping limitations section.

JS primitives

The following example demonstrates `[JSImport]` leveraging type mappings of several primitive JS types and the use of JSMarshalAs, where explicit mappings are required at compile time.

`PrimitivesShim.js`:

JavaScript

```
globalThis.counter = 0;

// Takes no parameters and returns nothing.
export function incrementCounter() {
  globalThis.counter += 1;
};

// Returns an int.
export function getCounter() { return globalThis.counter; };

// Takes a parameter and returns nothing. JS doesn't restrict the parameter
type,
// but we can restrict it in the .NET proxy, if desired.
export function logValue(value) { console.log(value); };

// Called for various .NET types to demonstrate mapping to JS primitive
types.
export function logValueAndType(value) { console.log(typeof value, value);
};
```

`PrimitivesInterop.cs`:

C#

```
using System;
using System.Runtime.InteropServices.JavaScript;
using System.Threading.Tasks;

public partial class PrimitivesInterop
{
    // Importing an existing JS method.
    [JSImport("globalThis.console.log")]
    public static partial void ConsoleLog([JSMarshalAs<JSType.Any>] object
value);
```

```
    // Importing static methods from a JS module.
    [JSImport("incrementCounter", "PrimitivesShim")]
    public static partial void IncrementCounter();

    [JSImport("getCounter", "PrimitivesShim")]
    public static partial int GetCounter();

    // The JS shim method name isn't required to match the C# method name.
    [JSImport("logValue", "PrimitivesShim")]
    public static partial void LogInt(int value);

    // A second mapping to the same JS method with compatible type.
    [JSImport("logValue", "PrimitivesShim")]
    public static partial void LogString(string value);

    // Accept any type as parameter. .NET types are mapped to JS types where
    // possible. Otherwise, they're marshalled as an untyped object
reference
    // to the .NET object proxy. The JS implementation logs to browser
console
    // the JS type and value to demonstrate results of marshalling.
    [JSImport("logValueAndType", "PrimitivesShim")]
    public static partial void LogValueAndType(
        [JSMarshalAs<JSType.Any>] object value);

    // Some types have multiple mappings and require explicit marshalling to
the
    // desired JS type. A long/Int64 can be mapped as either a Number or
BigInt.
    // Passing a long value to the above method generates an error at
runtime:
    // "ToJS for System.Int64 is not implemented." ("ToJS" means "to
JavaScript")
    // If the parameter declaration `Method(JSMarshalAs<JSType.Any>] long
value)`
    // is used, a compile-time error is generated:
    // "Type long is not supported by source-generated JS interop...."
    // Instead, explicitly map the long parameter to either a JSType.Number
or
    // JSType.BigInt. Note that runtime overflow errors are possible in JS
if the
    // C# value is too large.
    [JSImport("logValueAndType", "PrimitivesShim")]
    public static partial void LogValueAndTypeForNumber(
        [JSMarshalAs<JSType.Number>] long value);

    [JSImport("logValueAndType", "PrimitivesShim")]
    public static partial void LogValueAndTypeForBigInt(
        [JSMarshalAs<JSType.BigInt>] long value);
}

public static class PrimitivesUsage
{
    public static async Task Run()
    {
```

```
        // Ensure JS module loaded.
        await JSHost.ImportAsync("PrimitivesShim", "/PrimitivesShim.js");

        // Call a proxy to a static JS method, console.log().
        PrimitivesInterop.ConsoleLog("Printed from JSImport of
console.log()");

        // Basic examples of JS interop with an integer.
        PrimitivesInterop.IncrementCounter();
        int counterValue = PrimitivesInterop.GetCounter();
        PrimitivesInterop.LogInt(counterValue);
        PrimitivesInterop.LogString("I'm a string from .NET in your
browser!");

        // Mapping some other .NET types to JS primitives.
        PrimitivesInterop.LogValueAndType(true);
        PrimitivesInterop.LogValueAndType(0x3A); // Byte literal
        PrimitivesInterop.LogValueAndType('C');
        PrimitivesInterop.LogValueAndType((Int16)12);
        // JS Number has a lower max value and can generate overflow errors.
        PrimitivesInterop.LogValueAndTypeForNumber(9007199254740990L); //
Int64/Long
        // Next line: Int64/Long, JS BigInt supports larger numbers.
        PrimitivesInterop.LogValueAndTypeForBigInt(1234567890123456789L);//
        PrimitivesInterop.LogValueAndType(3.14f); // Single floating point
literal
        PrimitivesInterop.LogValueAndType(3.14d); // Double floating point
literal
        PrimitivesInterop.LogValueAndType("A string");
    }
}
```

In `Program.Main`:

```
C#

await PrimitivesUsage.Run();
```

The preceding example displays the following output in the browser's debug console:

> Printed from JSImport of console.log()
> 1
> I'm a string from .NET in your browser!
> boolean true
> number 58
> number 67
> number 12
> number 9007199254740990
> bigint 1234567890123456789n

> number 3.140000104904175
> number 3.14
> string A string

JS `Date` objects

The example in this section demonstrates importing methods which have a JS Date object as its return or parameter. Dates are marshalled across interop by-value, meaning they are copied in much the same way as JS primitives.

A `Date` object is timezone agnostic. A .NET DateTime is adjusted relative to its DateTimeKind when marshalled to a `Date`, but timezone information isn't preserved. Consider initializing a DateTime with a DateTimeKind.Utc or DateTimeKind.Local consistent with the value it represents.

`DateShim.js`:

JavaScript

```
export function incrementDay(date) {
  date.setDate(date.getDate() + 1);
  return date;
}

export function logValueAndType(value) {
  console.log("Date:", value)
}
```

`DateInterop.cs`:

C#

```
using System;
using System.Runtime.InteropServices.JavaScript;
using System.Threading.Tasks;

public partial class DateInterop
{
    [JSImport("incrementDay", "DateShim")]
    [return: JSMarshalAs<JSType.Date>] // Explicit JSMarshalAs for a return
type
    public static partial DateTime IncrementDay(
        [JSMarshalAs<JSType.Date>] DateTime date);

    [JSImport("logValueAndType", "DateShim")]
    public static partial void LogValueAndType(
        [JSMarshalAs<JSType.Date>] DateTime value);
```

```
}

public static class DateUsage
{
    public static async Task Run()
    {
        // Ensure JS module loaded.
        await JSHost.ImportAsync("DateShim", "/DateShim.js");

        // Basic examples of interop with a C# DateTime and JS Date.
        DateTime date = new DateTime(1968, 12, 21, 12, 51, 0,
DateTimeKind.Utc);
        DateInterop.LogValueAndType(date);
        date = DateInterop.IncrementDay(date);
        DateInterop.LogValueAndType(date);
    }
}
```

In `Program.Main`:

C#

```
await DateUsage.Run();
```

The preceding example displays the following output in the browser's debug console:

> Date: Sat Dec 21 1968 07:51:00 GMT-0500 (Eastern Standard Time)
> Date: Sun Dec 22 1968 07:51:00 GMT-0500 (Eastern Standard Time)

The preceding timezone information (`GMT-0500 (Eastern Standard Time)`) depends on local timezone of your computer/browser.

JS object references

Whenever a JS method returns an object reference, it's represented in .NET as a JSObject. The original JS object continues its lifetime within the JS boundary, while .NET code can access and modify it by reference through the JSObject. While the type itself exposes a limited API, the ability to hold a JS object reference and return or pass it across the interop boundary enables support for several interop scenarios.

The JSObject provides methods to access properties, but it doesn't provide direct access to instance methods. As the following `Summarize` method demonstrates, instance methods can be accessed indirectly by implementing a static method that takes the instance as a parameter.

`JSObjectShim.js`:

JavaScript

```
export function createObject() {
  return {
    name: "Example JS Object",
    answer: 41,
    question: null,
    summarize: function () {
      return `Question: "${this.question}" Answer: ${this.answer}`;
    }
  };
}

export function incrementAnswer(object) {
  object.answer += 1;
  // Don't return the modified object, since the reference is modified.
}

// Proxy an instance method call.
export function summarize(object) {
  return object.summarize();
}
```

`JSObjectInterop.cs`:

C#

```
using System;
using System.Runtime.InteropServices.JavaScript;
using System.Threading.Tasks;

public partial class JSObjectInterop
{
    [JSImport("createObject", "JSObjectShim")]
    public static partial JSObject CreateObject();

    [JSImport("incrementAnswer", "JSObjectShim")]
    public static partial void IncrementAnswer(JSObject jsObject);

    [JSImport("summarize", "JSObjectShim")]
    public static partial string Summarize(JSObject jsObject);

    [JSImport("globalThis.console.log")]
    public static partial void ConsoleLog([JSMarshalAs<JSType.Any>] object
value);
}

public static class JSObjectUsage
{
    public static async Task Run()
```

```
    {
        await JSHost.ImportAsync("JSObjectShim", "/JSObjectShim.js");

        JSObject jsObject = JSObjectInterop.CreateObject();
        JSObjectInterop.ConsoleLog(jsObject);
        JSObjectInterop.IncrementAnswer(jsObject);
        // An updated object isn't retrieved. The change is reflected in the
        // existing instance.
        JSObjectInterop.ConsoleLog(jsObject);

        // JSObject exposes several methods for interacting with properties.
        jsObject.SetProperty("question", "What is the answer?");
        JSObjectInterop.ConsoleLog(jsObject);

        // We can't directly JSImport an instance method on the jsObject,
but we
        // can pass the object reference and have the JS shim call the
instance
        // method.
        string summary = JSObjectInterop.Summarize(jsObject);
        Console.WriteLine("Summary: " + summary);
    }
}
```

In `Program.Main`:

C#

```
await JSObjectUsage.Run();
```

The preceding example displays the following output in the browser's debug console:

> {name: 'Example JS Object', answer: 41, question: null, Symbol(wasm cs_owned_js_handle): 5, summarize: *ƒ*}
> {name: 'Example JS Object', answer: 42, question: null, Symbol(wasm cs_owned_js_handle): 5, summarize: *ƒ*}
> {name: 'Example JS Object', answer: 42, question: 'What is the answer?', Symbol(wasm cs_owned_js_handle): 5, summarize: *ƒ*}
> Summary: Question: "What is the answer?" Answer: 42

Asynchronous interop

Many JS APIs are asynchronous and signal completion through either a callback, a Promise, or an async method. Ignoring asynchronous capabilities is often not an option, as subsequent code may depend upon the completion of the asynchronous operation and must be awaited.

JS methods using the `async` keyword or returning a Promise can be awaited in C# by a method returning a Task. As demonstrated below, the `async` keyword isn't used on the C# method with the `[JSImport]` attribute because it doesn't use the `await` keyword within it. However, consuming code calling the method would typically use the `await` keyword and be marked as `async`, as demonstrated in the `PromisesUsage` example.

JS with a callback, such as a `setTimeout`, can be wrapped in a Promise before returning from JS. Wrapping a callback in a Promise, as demonstrated in the function assigned to `Wait2Seconds`, is only appropriate when the callback is called exactly once. Otherwise, a C# Action can be passed to listen for a callback that may be called zero or many times, which is demonstrated in the Subscribing to JS events section.

`PromisesShim.js`:

JavaScript

```
export function wait2Seconds() {
  // This also demonstrates wrapping a callback-based API in a promise to
  // make it awaitable.
  return new Promise((resolve, reject) => {
    setTimeout(() => {
      resolve(); // Resolve promise after 2 seconds
    }, 2000);
  });
}

// Return a value via resolve in a promise.
export function waitGetString() {
  return new Promise((resolve, reject) => {
    setTimeout(() => {
      resolve("String From Resolve"); // Return a string via promise
    }, 500);
  });
}

export function waitGetDate() {
  return new Promise((resolve, reject) => {
    setTimeout(() => {
      resolve(new Date('1988-11-24')); // Return a date via promise
    }, 500);
  });
}

// Demonstrates an awaitable fetch.
export function fetchCurrentUrl() {
  // This method returns the promise returned by .then(*.text())
  // and .NET awaits the returned promise.
  return fetch(globalThis.window.location, { method: 'GET' })
    .then(response => response.text());
}
```

```
// .NET can await JS methods using the async/await JS syntax.
export async function asyncFunction() {
  await wait2Seconds();
}

// A Promise.reject can be used to signal failure and is bubbled to .NET
code
// as a JSException.
export function conditionalSuccess(shouldSucceed) {
  return new Promise((resolve, reject) => {
    setTimeout(() => {
      if (shouldSucceed)
        resolve(); // Success
      else
        reject("Reject: ShouldSucceed == false"); // Failure
    }, 500);
  });
}
```

Don't use the `async` keyword in the C# method signature. Returning Task or Task<TResult> is sufficient.

When calling asynchronous JS methods, we often want to wait until the JS method completes execution. If loading a resource or making a request, we likely want the following code to assume the action is completed.

If the JS shim returns a Promise, then C# can treat it as an awaitable Task/Task<TResult>.

`PromisesInterop.cs`:

C#

```
using System;
using System.Diagnostics;
using System.Runtime.InteropServices.JavaScript;
using System.Threading.Tasks;

public partial class PromisesInterop
{
    // For a promise with void return type, declare a Task return type:
    [JSImport("wait2Seconds", "PromisesShim")]
    public static partial Task Wait2Seconds();

    [JSImport("waitGetString", "PromisesShim")]
    public static partial Task<string> WaitGetString();

    // Some return types require a [return: JSMarshalAs...] declaring the
    // Promise's return type corresponding to Task<T>.
    [JSImport("waitGetDate", "PromisesShim")]
```

```
    [return: JSMarshalAs<JSType.Promise<JSType.Date>>()]
    public static partial Task<DateTime> WaitGetDate();

    [JSImport("fetchCurrentUrl", "PromisesShim")]
    public static partial Task<string> FetchCurrentUrl();

    [JSImport("asyncFunction", "PromisesShim")]
    public static partial Task AsyncFunction();

    [JSImport("conditionalSuccess", "PromisesShim")]
    public static partial Task ConditionalSuccess(bool shouldSucceed);
}

public static class PromisesUsage
{
    public static async Task Run()
    {
        await JSHost.ImportAsync("PromisesShim", "/PromisesShim.js");

        Stopwatch sw = new();
        sw.Start();

        await PromisesInterop.Wait2Seconds(); // Await Promise
        Console.WriteLine($"Waited {sw.Elapsed.TotalSeconds:#.0}s.");

        sw.Restart();
        string str =
            await PromisesInterop.WaitGetString(); // Await promise (string
return)
        Console.WriteLine(
            $"Waited {sw.Elapsed.TotalSeconds:#.0}s for WaitGetString:
'{str}'");

        sw.Restart();
        // Await promise with string return.
        DateTime date = await PromisesInterop.WaitGetDate();
        Console.WriteLine(
            $"Waited {sw.Elapsed.TotalSeconds:#.0}s for WaitGetDate:
'{date}'");

        // Await a JS fetch.
        string responseText = await PromisesInterop.FetchCurrentUrl();
        Console.WriteLine($"responseText.Length: {responseText.Length}");

        sw.Restart();

        await PromisesInterop.AsyncFunction(); // Await an async JS method
        Console.WriteLine(
            $"Waited {sw.Elapsed.TotalSeconds:#.0}s for AsyncFunction.");

        try
        {
            // Handle a promise rejection. Await an async JS method.
            await PromisesInterop.ConditionalSuccess(shouldSucceed: false);
        }
```

```
        catch (JSException ex) // Catch JS exception
        {
            Console.WriteLine($"JS Exception Caught: '{ex.Message}'");
        }
    }
}
```

In `Program.Main`:

C#

```
await PromisesUsage.Run();
```

The preceding example displays the following output in the browser's debug console:

> Waited 2.0s.
> Waited .5s for WaitGetString: 'String From Resolve'
> Waited .5s for WaitGetDate: '11/24/1988 12:00:00 AM'
> responseText.Length: 582
> Waited 2.0s for AsyncFunction.
> JS Exception Caught: 'Reject: ShouldSucceed == false'

Type mapping limitations

Some type mappings requiring nested generic types in the JSMarshalAs definition aren't currently supported. For example, returning a Promise for an array such as `[return: JSMarshalAs<JSType.Promise<JSType.Array<JSType.Number>>>()]` generates a compile-time error. An appropriate workaround varies depending on the scenario, but one option is to represent the array as a JSObject reference. This may be sufficient if accessing individual elements within .NET isn't necessary and the reference can be passed to other JS methods that act on the array. Alternatively, a dedicated method can take the JSObject reference as a parameter and return the materialized array, as demonstrated by the following `UnwrapJSObjectAsIntArray` example. In this case, the JS method has no type checking, and the developer has the responsibility to ensure a JSObject wrapping the appropriate array type is passed.

JavaScript

```
export function waitGetIntArrayAsObject() {
  return new Promise((resolve, reject) => {
    setTimeout(() => {
      resolve([1, 2, 3, 4, 5]); // Return an array from the Promise
    }, 500);
  });
```

```
}

export function unwrapJSObjectAsIntArray(jsObject) {
  return jsObject;
}
```

C#

```
// Not supported, generates compile-time error.
// [JSImport("waitGetArray", "PromisesShim")]
// [return: JSMarshalAs<JSType.Promise<JSType.Array<JSType.Number>>>()]
// public static partial Task<int[]> WaitGetIntArray();

// Workaround, take the return the call and pass it to
UnwrapJSObjectAsIntArray.
// Return a JSObject reference to a JS number array.
[JSImport("waitGetIntArrayAsObject", "PromisesShim")]
[return: JSMarshalAs<JSType.Promise<JSType.Object>>()]
public static partial Task<JSObject> WaitGetIntArrayAsObject();

// Takes a JSObject reference to a JS number array, and returns the array as
a C#
// int array.
[JSImport("unwrapJSObjectAsIntArray", "PromisesShim")]
[return: JSMarshalAs<JSType.Array<JSType.Number>>()]
public static partial int[] UnwrapJSObjectAsIntArray(JSObject intArray);
//...
```

In `Program.Main`:

C#

```
JSObject arrayAsJSObject = await PromisesInterop.WaitGetIntArrayAsObject();
int[] intArray = PromisesInterop.UnwrapJSObjectAsIntArray(arrayAsJSObject);
```

Performance considerations

Marshalling of calls and the overhead of tracking objects across the interop boundary is more expensive than native .NET operations but should still demonstrate acceptable performance for a typical web app with moderate demand.

Object proxies, such as JSObject, which maintain references across the interop boundary, have additional memory overhead and impact how garbage collection affects these objects. Additionally, available memory might be exhausted without triggering garbage collection in some scenarios because memory pressure from JS and .NET isn't shared. This risk is significant when an excessive number of large objects are referenced

across the interop boundary by relatively small JS objects, or vice versa where large .NET objects are referenced by JS proxies. In such cases, we recommend following deterministic disposal patterns with `using` scopes leveraging the IDisposable interface on JS objects.

The following benchmarks, which leverage earlier example code, demonstrate that interop operations are roughly an order of magnitude slower than those that remain within the .NET boundary, but the interop operations remain relatively fast. Additionally, consider that a user's device capabilities impact performance.

`JSObjectBenchmark.cs`:

C#

```
using System;
using System.Diagnostics;

public static class JSObjectBenchmark
{
    public static void Run()
    {
        Stopwatch sw = new();
        var jsObject = JSObjectInterop.CreateObject();

        sw.Start();

        for (int i = 0; i < 1000000; i++)
        {
            JSObjectInterop.IncrementAnswer(jsObject);
        }

        sw.Stop();

        Console.WriteLine(
            $"JS interop elapsed time: {sw.Elapsed.TotalSeconds:#.0000}
seconds " +
            $"at {sw.Elapsed.TotalMilliseconds / 1000000d:#.000000} ms per "
+
            "operation");

        var pocoObject =
            new PocoObject { Question = "What is the answer?", Answer = 41
};
        sw.Restart();

        for (int i = 0; i < 1000000; i++)
        {
            pocoObject.IncrementAnswer();
        }

        sw.Stop();
```

```
        Console.WriteLine($".NET elapsed time:
{sw.Elapsed.TotalSeconds:#.0000} " +
            $"seconds at {sw.Elapsed.TotalMilliseconds / 1000000d:#.000000}
ms " +
            "per operation");

        Console.WriteLine($"Begin Object Creation");

        sw.Restart();

        for (int i = 0; i < 1000000; i++)
        {
            var jsObject2 = JSObjectInterop.CreateObject();
            JSObjectInterop.IncrementAnswer(jsObject2);
        }

        sw.Stop();

        Console.WriteLine(
            $"JS interop elapsed time: {sw.Elapsed.TotalSeconds:#.0000}
seconds " +
            $"at {sw.Elapsed.TotalMilliseconds / 1000000d:#.000000} ms per "
+
            "operation");

        sw.Restart();

        for (int i = 0; i < 1000000; i++)
        {
            var pocoObject2 =
                new PocoObject { Question = "What is the answer?", Answer =
0 };
            pocoObject2.IncrementAnswer();
        }

        sw.Stop();
        Console.WriteLine(
            $".NET elapsed time: {sw.Elapsed.TotalSeconds:#.0000} seconds at
" +
            $"{sw.Elapsed.TotalMilliseconds / 1000000d:#.000000} ms per
operation");
    }

    public class PocoObject // Plain old CLR object
    {
        public string Question { get; set; }
        public int Answer { get; set; }

        public void IncrementAnswer() => Answer += 1;
    }
}
```

In `Program.Main`:

C#

```
JSObjectBenchmark.Run();
```

The preceding example displays the following output in the browser's debug console:

> JS interop elapsed time: .2536 seconds at .000254 ms per operation
> .NET elapsed time: .0210 seconds at .000021 ms per operation
> Begin Object Creation
> JS interop elapsed time: 2.1686 seconds at .002169 ms per operation
> .NET elapsed time: .1089 seconds at .000109 ms per operation

Subscribing to JS events

.NET code can subscribe to JS events and handle JS events by passing a C# Action to a JS function to act as a handler. The JS shim code handles subscribing to the event.

> ⚠ **Warning**
>
> Interacting with individual properties of the DOM via JS interop, as the guidance in this section demonstrates, is relatively slow and may lead to the creation of many proxies that create high garbage collection pressure. The following pattern isn't generally recommended. Use the following pattern for no more than a few elements. For more information, see the **Performance considerations** section.

A nuance of `removeEventListener` is that it requires a reference to the function previously passed to `addEventListener`. When a C# Action is passed across the interop boundary, it's wrapped in a JS proxy object. Therefore, passing the same C# Action to both `addEventListener` and `removeEventListener` results in generating two different JS proxy objects wrapping the Action. These references are different, thus `removeEventListener` isn't able to find the event listener to remove. To address this problem, the following examples wrap the C# Action in a JS function and return the reference as a JSObject from the subscribe call to pass later to the unsubscribe call. Because the C# Action is returned and passed as a JSObject, the same reference is used for both calls, and the event listener can be removed.

`EventsShim.js`:

JavaScript

```
export function subscribeEventById(elementId, eventName, listenerFunc) {
  const elementObj = document.getElementById(elementId);

  // Need to wrap the Managed C# action in JS func (only because it is being
  // returned).
  let handler = function (event) {
    listenerFunc(event.type, event.target.id); // Decompose object to
primitives
  }.bind(elementObj);

  elementObj.addEventListener(eventName, handler, false);
  // Return JSObject reference so it can be used for removeEventListener
later.
  return handler;
}

// Param listenerHandler must be the JSObject reference returned from the
prior
// SubscribeEvent call.
export function unsubscribeEventById(elementId, eventName, listenerHandler)
{
  const elementObj = document.getElementById(elementId);
  elementObj.removeEventListener(eventName, listenerHandler, false);
}

export function triggerClick(elementId) {
  const elementObj = document.getElementById(elementId);
  elementObj.click();
}

export function getElementById(elementId) {
  return document.getElementById(elementId);
}

export function subscribeEvent(elementObj, eventName, listenerFunc) {
  let handler = function (e) {
    listenerFunc(e);
  }.bind(elementObj);

  elementObj.addEventListener(eventName, handler, false);
  return handler;
}

export function unsubscribeEvent(elementObj, eventName, listenerHandler) {
  return elementObj.removeEventListener(eventName, listenerHandler, false);
}

export function subscribeEventFailure(elementObj, eventName, listenerFunc) {
  // It's not strictly required to wrap the C# action listenerFunc in a JS
  // function.
  elementObj.addEventListener(eventName, listenerFunc, false);
  // If you need to return the wrapped proxy object, you will receive an
error
  // when it tries to wrap the existing proxy in an additional proxy:
```

```
  // Error: "JSObject proxy of ManagedObject proxy is not supported."
  return listenerFunc;
}
```

`EventsInterop.cs`:

C#

```
using System;
using System.Runtime.InteropServices.JavaScript;
using System.Threading.Tasks;

public partial class EventsInterop
{
    [JSImport("subscribeEventById", "EventsShim")]
    public static partial JSObject SubscribeEventById(string elementId,
        string eventName,
        [JSMarshalAs<JSType.Function<JSType.String, JSType.String>>]
        Action<string, string> listenerFunc);

    [JSImport("unsubscribeEventById", "EventsShim")]
    public static partial void UnsubscribeEventById(string elementId,
        string eventName, JSObject listenerHandler);

    [JSImport("triggerClick", "EventsShim")]
    public static partial void TriggerClick(string elementId);

    [JSImport("getElementById", "EventsShim")]
    public static partial JSObject GetElementById(string elementId);

    [JSImport("subscribeEvent", "EventsShim")]
    public static partial JSObject SubscribeEvent(JSObject htmlElement,
        string eventName,
        [JSMarshalAs<JSType.Function<JSType.Object>>]
        Action<JSObject> listenerFunc);

    [JSImport("unsubscribeEvent", "EventsShim")]
    public static partial void UnsubscribeEvent(JSObject htmlElement,
        string eventName, JSObject listenerHandler);
}

public static class EventsUsage
{
    public static async Task Run()
    {
        await JSHost.ImportAsync("EventsShim", "/EventsShim.js");

        Action<string, string> listenerFunc = (eventName, elementId) =>
            Console.WriteLine(
                $"In C# event listener: Event {eventName} from ID
{elementId}");

        // Assumes two buttons exist on the page with ids of "btn1" and
```

```
"btn2"
        JSObject listenerHandler1 =
            EventsInterop.SubscribeEventById("btn1", "click", listenerFunc);
        JSObject listenerHandler2 =
            EventsInterop.SubscribeEventById("btn2", "click", listenerFunc);
        Console.WriteLine("Subscribed to btn1 & 2.");
        EventsInterop.TriggerClick("btn1");
        EventsInterop.TriggerClick("btn2");

        EventsInterop.UnsubscribeEventById("btn2", "click",
listenerHandler2);
        Console.WriteLine("Unsubscribed btn2.");
        EventsInterop.TriggerClick("btn1");
        EventsInterop.TriggerClick("btn2"); // Doesn't trigger because
unsubscribed
        EventsInterop.UnsubscribeEventById("btn1", "click",
listenerHandler1);
        // Pitfall: Using a different handler for unsubscribe silently
fails.
        // EventsInterop.UnsubscribeEventById("btn1", "click",
listenerHandler2);

        // With JSObject as event target and event object.
        Action<JSObject> listenerFuncForElement = (eventObj) =>
        {
            string eventType = eventObj.GetPropertyAsString("type");
            JSObject target = eventObj.GetPropertyAsJSObject("target");
            Console.WriteLine(
                $"In C# event listener: Event {eventType} from " +
                $"ID {target.GetPropertyAsString("id")}");
        };

        JSObject htmlElement = EventsInterop.GetElementById("btn1");
        JSObject listenerHandler3 = EventsInterop.SubscribeEvent(
            htmlElement, "click", listenerFuncForElement);
        Console.WriteLine("Subscribed to btn1.");
        EventsInterop.TriggerClick("btn1");
        EventsInterop.UnsubscribeEvent(htmlElement, "click",
listenerHandler3);
        Console.WriteLine("Unsubscribed btn1.");
        EventsInterop.TriggerClick("btn1");
    }
}
```

In `Program.Main`:

C#

```
await EventsUsage.Run();
```

The preceding example displays the following output in the browser's debug console:

> Subscribed to btn1 & 2.
> In C# event listener: Event click from ID btn1
> In C# event listener: Event click from ID btn2
> Unsubscribed btn2.
> In C# event listener: Event click from ID btn1
> Subscribed to btn1.
> In C# event listener: Event click from ID btn1
> Unsubscribed btn1.

JS `[JSImport]`/`[JSExport]` interop scenarios

The following articles focus on running a .NET WebAssembly module in a JS host, such as a browser:

- JavaScript `[JSImport]`/`[JSExport]` interop with a WebAssembly Browser App project
- JavaScript JSImport/JSExport interop with ASP.NET Core Blazor

JavaScript `[JSImport]`/`[JSExport]` interop with a WebAssembly Browser App project

Article • 08/22/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article explains how to setup a WebAssembly Browser App project to run .NET from JavaScript (JS) using JS `[JSImport]`/`[JSExport]` interop. For additional information and examples, see JavaScript `[JSImport]`/`[JSExport]` interop in .NET WebAssembly.

For additional guidance, see the Configuring and hosting .NET WebAssembly applications guidance in the .NET Runtime (`dotnet/runtime`) GitHub repository.

Existing JS apps can use the expanded client-side WebAssembly support to reuse .NET libraries from JS or to build novel .NET-based apps and frameworks.

> **Note**
>
> This article focuses on running .NET from JS apps without any dependency on Blazor. For guidance on using `[JSImport]`/`[JSExport]` interop in Blazor WebAssembly apps, see JavaScript JSImport/JSExport interop with ASP.NET Core Blazor.

These approaches are appropriate when you only expect the Blazor app to run on WebAssembly (WASM). Libraries can make a runtime check to determine if the app is running on WASM by calling OperatingSystem.IsBrowser.

Prerequisites

.NET SDK (latest version)

Install the `wasm-tools` workload in an administrative command shell, which brings in the related MSBuild targets:

.NET CLI

```
dotnet workload install wasm-tools
```

The tools can also be installed via Visual Studio's installer under the **ASP.NET and web development** workload in the Visual Studio installer. Select the **.NET WebAssembly build tools** option from the list of optional components.

Optionally, install the `wasm-experimental` workload, which adds the following experimental project templates:

- *WebAssembly Browser App* for getting started with .NET on WebAssembly in a browser app.
- *WebAssembly Console App* for getting started in a Node.js-based console app.

After installing the workload, these new templates can be selected when creating a new project. This workload isn't required if you plan to integrate JS `[JSImport]`/`[JSExport]` interop into an existing JS app.

.NET CLI

```
dotnet workload install wasm-experimental
```

The templates can also be installed from the Microsoft.NET.Runtime.WebAssembly.Templates NuGet package with the following command:

.NET CLI

```
dotnet new install Microsoft.NET.Runtime.WebAssembly.Templates
```

For more information, see the Experimental workload and project templates section.

Namespace

The JS interop API described in this article is controlled by attributes in the System.Runtime.InteropServices.JavaScript namespace.

Project configuration

To configure a project (`.csproj`) to enable JS interop:

- Set the target framework moniker (`{TARGET FRAMEWORK}` placeholder):

  ```xml
  <TargetFramework>{TARGET FRAMEWORK}</TargetFramework>
  ```

  .NET 7 (`net7.0`) or later is supported.

- Enable the AllowUnsafeBlocks property, which permits the code generator in the Roslyn compiler to use pointers for JS interop:

  ```xml
  <AllowUnsafeBlocks>true</AllowUnsafeBlocks>
  ```

  > **⚠ Warning**
  >
  > The JS interop API requires enabling AllowUnsafeBlocks. Be careful when implementing your own unsafe code in .NET apps, which can introduce security and stability risks. For more information, see Unsafe code, pointer types, and function pointers.

The following is an example project file (`.csproj`) after configuration. The `{TARGET FRAMEWORK}` placeholder is the target framework:

```xml
<Project Sdk="Microsoft.NET.Sdk.WebAssembly">

  <PropertyGroup>
    <TargetFramework>{TARGET FRAMEWORK}</TargetFramework>
    <AllowUnsafeBlocks>true</AllowUnsafeBlocks>
  </PropertyGroup>

</Project>
```

JavaScript interop on WASM

APIs in the following example are imported from `dotnet.js`. These APIs enable you to set up named modules that can be imported into your C# code and call into methods

exposed by your .NET code, including `Program.Main`.

> **ⓘ Important**
>
> "Import" and "export" throughout this article are defined from the perspective of .NET:
>
> - An app imports JS methods so that they can be called from .NET.
> - The app exports .NET methods so that they can be called from JS.

In the following example:

- The `dotnet.js` file is used to create and start the .NET WebAssembly runtime. `dotnet.js` is generated as part of the app's build output.

  > **ⓘ Important**
  >
  > To integrate with an existing app, copy the contents of the publish output folder† to the existing app's deployment assets so that it can be served along with the rest of the app. For production deployments, publish the app with the `dotnet publish -c Release` command in a command shell and deploy the output folder's contents with the app.
  >
  > †The publish output folder is the target location of your publish profile. The default for a **Release** profile in .NET 8 or later is `bin/Release/{TARGET FRAMEWORK}/publish`, where the `{TARGET FRAMEWORK}` placeholder is the target framework (for example, `net8.0`).

- `dotnet.create()` sets up the .NET WebAssembly runtime.

- `setModuleImports` associates a name with a module of JS functions for import into .NET. The JS module contains a `dom.setInnerText` function, which accepts and element selector and time to display the current stopwatch time in the UI. The name of the module can be any string (it doesn't need to be a file name), but it must match the name used with the `JSImportAttribute` (explained later in this article). The `dom.setInnerText` function is imported into C# and called by the C# method `SetInnerText`. The `SetInnerText` method is shown later in this section.

- `exports.StopwatchSample.Reset()` calls into .NET (`StopwatchSample.Reset`) from JS. The `Reset` C# method restarts the stopwatch if it's running or resets it if it isn't

running. The `Reset` method is shown later in this section.

- `exports.StopwatchSample.Toggle()` calls into .NET (`StopwatchSample.Toggle`) from JS. The `Toggle` C# method starts or stops the stopwatch depending on if it's currently running or not. The `Toggle` method is shown later in this section.
- `runMain()` runs `Program.Main`.

JS module:

JavaScript

```
import { dotnet } from './_framework/dotnet.js'

const { setModuleImports, getAssemblyExports, getConfig, runMain } = await
dotnet
  .withApplicationArguments("start")
  .create();

setModuleImports('main.js', {
  dom: {
    setInnerText: (selector, time) =>
      document.querySelector(selector).innerText = time
  }
});

const config = getConfig();
const exports = await getAssemblyExports(config.mainAssemblyName);

document.getElementById('reset').addEventListener('click', e => {
  exports.StopwatchSample.Reset();
  e.preventDefault();
});

const pauseButton = document.getElementById('pause');
pauseButton.addEventListener('click', e => {
  const isRunning = exports.StopwatchSample.Toggle();
  pauseButton.innerText = isRunning ? 'Pause' : 'Start';
  e.preventDefault();
});

await runMain();
```

To import a JS function so it can be called from C#, use the new JSImportAttribute on a matching method signature. The first parameter to the JSImportAttribute is the name of the JS function to import and the second parameter is the name of the module.

In the following example, the `dom.setInnerText` function is called from the `main.js` module when `SetInnerText` method is called:

C#

```
[JSImport("dom.setInnerText", "main.js")]
internal static partial void SetInnerText(string selector, string content);
```

In the imported method signature, you can use .NET types for parameters and return values, which are marshalled automatically by the runtime. Use JSMarshalAsAttribute<T> to control how the imported method parameters are marshalled. For example, you might choose to marshal a `long` as System.Runtime.InteropServices.JavaScript.JSType.Number or System.Runtime.InteropServices.JavaScript.JSType.BigInt. You can pass Action/Func<TResult> callbacks as parameters, which are marshalled as callable JS functions. You can pass both JS and managed object references, and they are marshaled as proxy objects, keeping the object alive across the boundary until the proxy is garbage collected. You can also import and export asynchronous methods with a Task result, which are marshaled as JS promises. Most of the marshalled types work in both directions, as parameters and as return values, on both imported and exported methods.

For additional type mapping information and examples, see JavaScript `[JSImport]`/`[JSExport]` interop in .NET WebAssembly.

Functions accessible on the global namespace can be imported by using the globalThis prefix in the function name and by using the `[JSImport]` attribute without providing a module name. In the following example, console.log is prefixed with `globalThis`. The imported function is called by the C# `Log` method, which accepts a C# string message (`message`) and marshalls the C# string to a JS String for `console.log`:

C#

```
[JSImport("globalThis.console.log")]
internal static partial void Log([JSMarshalAs<JSType.String>] string
message);
```

To export a .NET method so it can be called from JS, use the JSExportAttribute.

In the following example, each method is exported to JS and can be called from JS functions:

- The `Toggle` method starts or stops the stopwatch depending on its running state.
- The `Reset` method restarts the stopwatch if it's running or resets it if it isn't running.
- The `IsRunning` method indicates if the stopwatch is running.

C#

```
[JSExport]
internal static bool Toggle()
{
    if (stopwatch.IsRunning)
    {
        stopwatch.Stop();
        return false;
    }
    else
    {
        stopwatch.Start();
        return true;
    }
}

[JSExport]
internal static void Reset()
{
    if (stopwatch.IsRunning)
        stopwatch.Restart();
    else
        stopwatch.Reset();

    Render();
}

[JSExport]
internal static bool IsRunning() => stopwatch.IsRunning;
```

Experimental workload and project templates

To demonstrate the JS interop functionality and obtain JS interop project templates, install the `wasm-experimental` workload:

.NET CLI

```
dotnet workload install wasm-experimental
```

The `wasm-experimental` workload contains two project templates: `wasmbrowser` and `wasmconsole`. These templates are experimental at this time, which means the developer workflow for the templates is evolving. However, the .NET and JS APIs used in the templates are supported in .NET 8 and provide a foundation for using .NET on WASM from JS.

The templates can also be installed from the Microsoft.NET.Runtime.WebAssembly.Templates NuGet package with the following command:

.NET CLI

```
dotnet new install Microsoft.NET.Runtime.WebAssembly.Templates
```

Browser app

You can create a browser app with the `wasmbrowser` template from the command line, which creates a web app that demonstrates using .NET and JS together in a browser:

.NET CLI

```
dotnet new wasmbrowser
```

Alternatively in Visual Studio, you can create the app using the **WebAssembly Browser App** project template.

Build the app from Visual Studio or by using the .NET CLI:

.NET CLI

```
dotnet build
```

Build and run the app from Visual Studio or by using the .NET CLI:

.NET CLI

```
dotnet run
```

Alternatively, install and use the dotnet serve command:

.NET CLI

```
dotnet serve -d:bin/$(Configuration)/{TARGET FRAMEWORK}/publish
```

In the preceding example, the `{TARGET FRAMEWORK}` placeholder is the target framework moniker.

Node.js console app

You can create a console app with the `wasmconsole` template, which creates an app that runs under WASM as a Node.js or V8 console app:

.NET CLI

```
dotnet new wasmconsole
```

Alternatively in Visual Studio, you can create the app using the **WebAssembly Console App** project template.

Build the app from Visual Studio or by using the .NET CLI:

.NET CLI

```
dotnet build
```

Build and run the app from Visual Studio or by using the .NET CLI:

.NET CLI

```
dotnet run
```

Alternatively, start any static file server from the publish output directory that contains the `main.mjs` file:

```
node bin/$(Configuration)/{TARGET FRAMEWORK}/{PATH}/main.mjs
```

In the preceding example, the `{TARGET FRAMEWORK}` placeholder is the target framework moniker, and the `{PATH}` placeholder is the path to the `main.mjs` file.

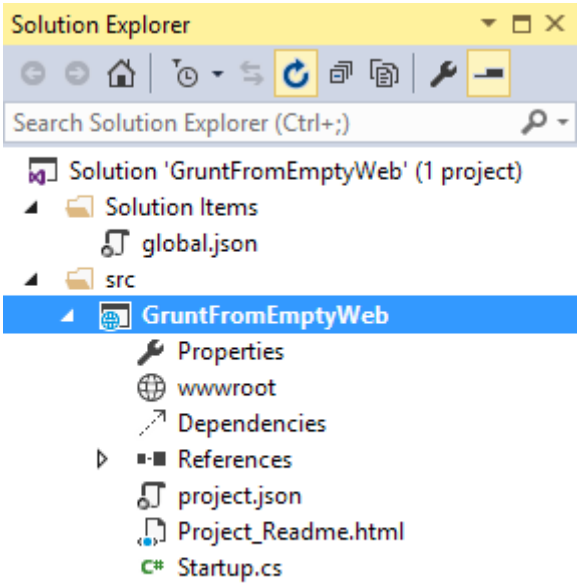
Use Grunt in ASP.NET Core

Article • 09/27/2024

Grunt is a JavaScript task runner that automates script minification, TypeScript compilation, code quality "lint" tools, CSS pre-processors, and just about any repetitive chore that needs doing to support client development. Grunt is fully supported in Visual Studio.

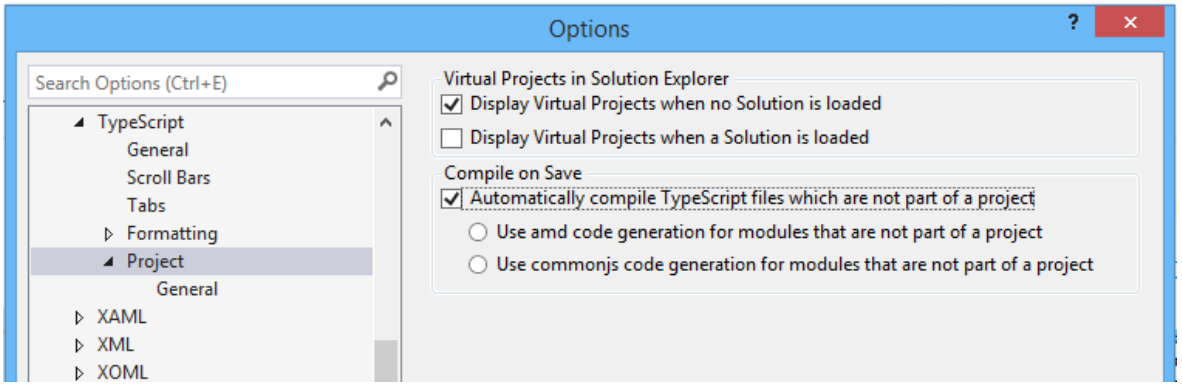
This example uses an empty ASP.NET Core project as its starting point, to show how to automate the client build process from scratch.



The finished example cleans the target deployment directory, combines JavaScript files, checks code quality, condenses JavaScript file content and deploys to the root of your web application. We will use the following packages:

- **grunt**: The Grunt task runner package.
- **grunt-contrib-clean**: A plugin that removes files or directories.
- **grunt-contrib-jshint**: A plugin that reviews JavaScript code quality.
- **grunt-contrib-concat**: A plugin that joins files into a single file.
- **grunt-contrib-uglify**: A plugin that minifies JavaScript to reduce size.
- **grunt-contrib-watch**: A plugin that watches file activity.

Preparing the application



To begin, set up a new empty web application and add TypeScript example files. TypeScript files are automatically compiled into JavaScript using default Visual Studio settings and will be our raw material to process using Grunt.

1. In Visual Studio, create a new `ASP.NET Web Application`.
2. In the **New ASP.NET Project** dialog, select the ASP.NET Core **Empty** template and click the OK button.
3. In the Solution Explorer, review the project structure. The `\src` folder includes empty `wwwroot` and `Dependencies` nodes.

4. Add a new folder named `TypeScript` to your project directory.

5. Before adding any files, make sure that Visual Studio has the option 'compile on save' for TypeScript files checked. Navigate to **Tools** > **Options** > **Text Editor** > **Typescript** > **Project**:

6. Right-click the `TypeScript` directory and select **Add** > **New Item** from the context menu. Select the **JavaScript file** item and name the file `Tastes.ts` (note the *.ts extension). Copy the line of TypeScript code below into the file (when you save, a new `Tastes.js` file will appear with the JavaScript source).

```TypeScript
enum Tastes { Sweet, Sour, Salty, Bitter }
```

7. Add a second file to the **TypeScript** directory and name it `Food.ts`. Copy the code below into the file.

```TypeScript
```

```
class Food {
  constructor(name: string, calories: number) {
    this._name = name;
    this._calories = calories;
  }

  private _name: string;
  get Name() {
    return this._name;
  }

  private _calories: number;
  get Calories() {
    return this._calories;
  }

  private _taste: Tastes;
  get Taste(): Tastes { return this._taste }
  set Taste(value: Tastes) {
    this._taste = value;
  }
}
```

Configuring NPM

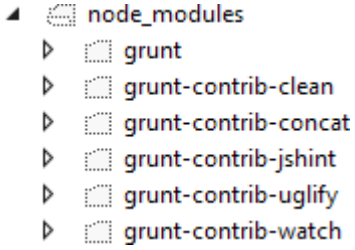
Next, configure NPM to download grunt and grunt-tasks.

1. In the Solution Explorer, right-click the project and select **Add** > **New Item** from the context menu. Select the **NPM configuration file** item, leave the default name, `package.json`, and click the **Add** button.

2. In the `package.json` file, inside the `devDependencies` object braces, enter "grunt". Select `grunt` from the Intellisense list and press the Enter key. Visual Studio will quote the grunt package name, and add a colon. To the right of the colon, select the latest stable version of the package from the top of the Intellisense list (press `Ctrl-Space` if Intellisense doesn't appear).

> ⓘ Note

> NPM uses semantic versioning to organize dependencies. Semantic versioning, also known as SemVer, identifies packages with the numbering scheme <major>.<minor>.<patch>. Intellisense simplifies semantic versioning by showing only a few common choices. The top item in the Intellisense list (0.4.5 in the example above) is considered the latest stable version of the package. The caret (^) symbol matches the most recent major version and the tilde (~) matches the most recent minor version. See the NPM semver version parser reference as a guide to the full expressivity that SemVer provides.



3. Add more dependencies to load grunt-contrib-* packages for *clean*, *jshint*, *concat*, *uglify*, and *watch* as shown in the example below. The versions don't need to match the example.

   JSON

   ```
   "devDependencies": {
     "grunt": "0.4.5",
     "grunt-contrib-clean": "0.6.0",
     "grunt-contrib-jshint": "0.11.0",
     "grunt-contrib-concat": "0.5.1",
     "grunt-contrib-uglify": "0.8.0",
     "grunt-contrib-watch": "0.6.1"
   }
   ```

4. Save the `package.json` file.

The packages for each `devDependencies` item will download, along with any files that each package requires. You can find the package files in the *node_modules* directory by enabling the **Show All Files** button in **Solution Explorer**.

> **Note**
>
> If you need to, you can manually restore dependencies in **Solution Explorer** by right-clicking on `Dependencies\NPM` and selecting the **Restore Packages** menu option.

Configuring Grunt

Grunt is configured using a manifest named `Gruntfile.js` that defines, loads and registers tasks that can be run manually or configured to run automatically based on events in Visual Studio.

1. Right-click the project and select **Add** > **New Item**. Select the **JavaScript File** item template, change the name to `Gruntfile.js`, and click the **Add** button.

2. Add the following code to `Gruntfile.js`. The `initConfig` function sets options for each package, and the remainder of the module loads and register tasks.

   JavaScript

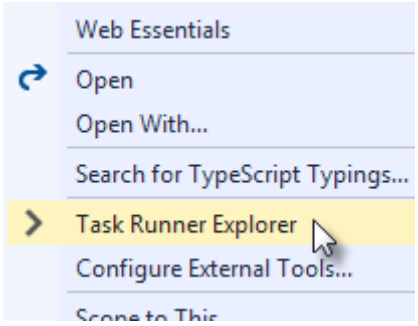
   ```
   module.exports = function (grunt) {
     grunt.initConfig({
     });
   };
   ```

3. Inside the `initConfig` function, add options for the `clean` task as shown in the example `Gruntfile.js` below. The `clean` task accepts an array of directory strings. This task removes files from *wwwroot/lib* and removes the entire */temp* directory.

   JavaScript

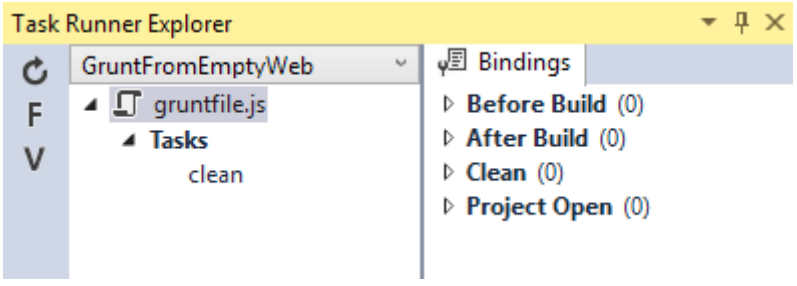
   ```
   module.exports = function (grunt) {
     grunt.initConfig({
       clean: ["wwwroot/lib/*", "temp/"],
     });
   };
   ```

4. Below the `initConfig` function, add a call to `grunt.loadNpmTasks`. This will make the task runnable from Visual Studio.

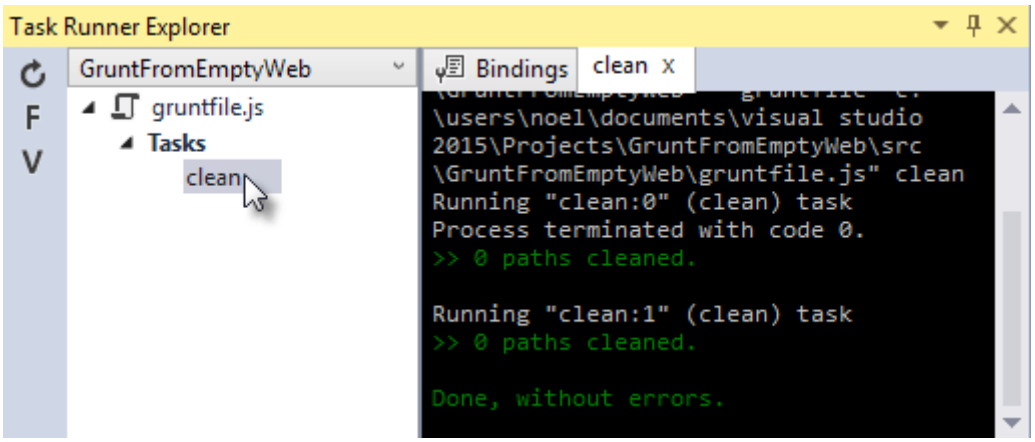


```
JavaScript

grunt.loadNpmTasks("grunt-contrib-clean");
```



5. Save `Gruntfile.js`. The file should look something like the screenshot below.



6. Right-click `Gruntfile.js` and select **Task Runner Explorer** from the context menu. The **Task Runner Explorer** window will open.

7. Verify that `clean` shows under **Tasks** in the **Task Runner Explorer**.

8. Right-click the clean task and select **Run** from the context menu. A command window displays progress of the task.

> **Note**
>
> There are no files or directories to clean yet. If you like, you can manually create them in the Solution Explorer and then run the clean task as a test.

9. In the `initConfig` function, add an entry for `concat` using the code below.

   The `src` property array lists files to combine, in the order that they should be combined. The `dest` property assigns the path to the combined file that's produced.

   JavaScript

```
concat: {
  all: {
    src: ['TypeScript/Tastes.js', 'TypeScript/Food.js'],
    dest: 'temp/combined.js'
  }
},
```

> **Note**
>
> The `all` property in the code above is the name of a target. Targets are used in some Grunt tasks to allow multiple build environments. You can view the built-in targets using IntelliSense or assign your own.

10. Add the `jshint` task using the code below.

    The jshint `code-quality` utility is run against every JavaScript file found in the *temp* directory.

    JavaScript

```
jshint: {
  files: ['temp/*.js'],
  options: {
    '-W069': false,
  }
},
```

> **Note**
>
> The option "-W069" is an error produced by jshint when JavaScript uses bracket syntax to assign a property instead of dot notation, `Tastes["Sweet"]` instead of `Tastes.Sweet`. The option turns off the warning to allow the rest of the process to continue.

11. Add the `uglify` task using the code below.

    The task minifies the `combined.js` file found in the temp directory and creates the result file in wwwroot/lib following the standard naming convention *<file name>.min.js*.

    JavaScript

    ```
    uglify: {
     all: {
       src: ['temp/combined.js'],
       dest: 'wwwroot/lib/combined.min.js'
     }
    },
    ```

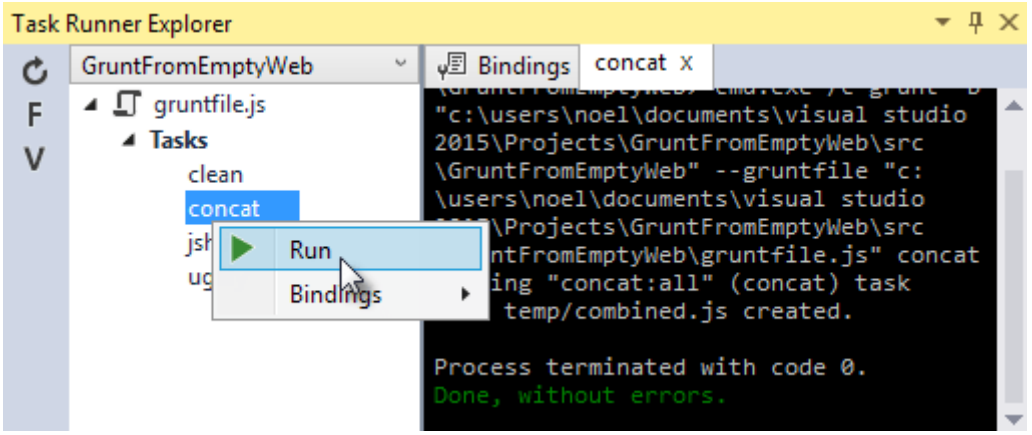
12. Under the call to `grunt.loadNpmTasks` that loads `grunt-contrib-clean`, include the same call for jshint, concat, and uglify using the code below.

    JavaScript

    ```
    grunt.loadNpmTasks('grunt-contrib-jshint');
    grunt.loadNpmTasks('grunt-contrib-concat');
    grunt.loadNpmTasks('grunt-contrib-uglify');
    ```

13. Save `Gruntfile.js`. The file should look something like the example below.

Gruntfile.js



module | exports(grunt)

```
module.exports = function (grunt) {
    grunt.initConfig({
        clean: ["wwwroot/lib/*", "temp/"],
        concat: {
            all: {
                src: ['TypeScript/Tastes.js', 'TypeScript/Food.js'],
                dest: 'temp/combined.js'
            }
        },
        jshint: { files: ['temp/*.js'], options: { '-W069': false, } },
        uglify: {
            all: {
                src: ['temp/combined.js'],
                dest: 'wwwroot/lib/combined.min.js'
            }
        }
    });

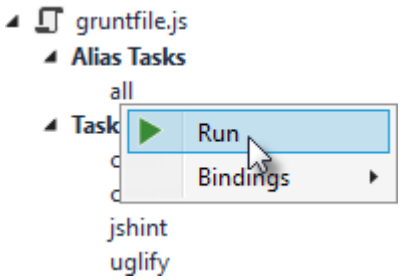
    grunt.loadNpmTasks('grunt-contrib-clean');
    grunt.loadNpmTasks('grunt-contrib-jshint');
    grunt.loadNpmTasks('grunt-contrib-concat');
    grunt.loadNpmTasks('grunt-contrib-uglify');
};
```

110 %

14. Notice that the **Task Runner Explorer** Tasks list includes `clean`, `concat`, `jshint` and `uglify` tasks. Run each task in order and observe the results in **Solution Explorer**. Each task should run without errors.

The concat task creates a new `combined.js` file and places it into the temp directory. The `jshint` task simply runs and doesn't produce output. The `uglify` task creates a new `combined.min.js` file and places it into *wwwroot/lib*. On completion, the solution should look something like the screenshot below:

> **Note**
>
> For more information on the options for each package, visit https://www.npmjs.com/ and lookup the package name in the search box on the main page. For example, you can look up the grunt-contrib-clean package to get a documentation link that explains all of its parameters.



All together now

Use the Grunt `registerTask()` method to run a series of tasks in a particular sequence. For example, to run the example steps above in the order clean -> concat -> jshint -> uglify, add the code below to the module. The code should be added to the same level as the loadNpmTasks() calls, outside initConfig.

JavaScript

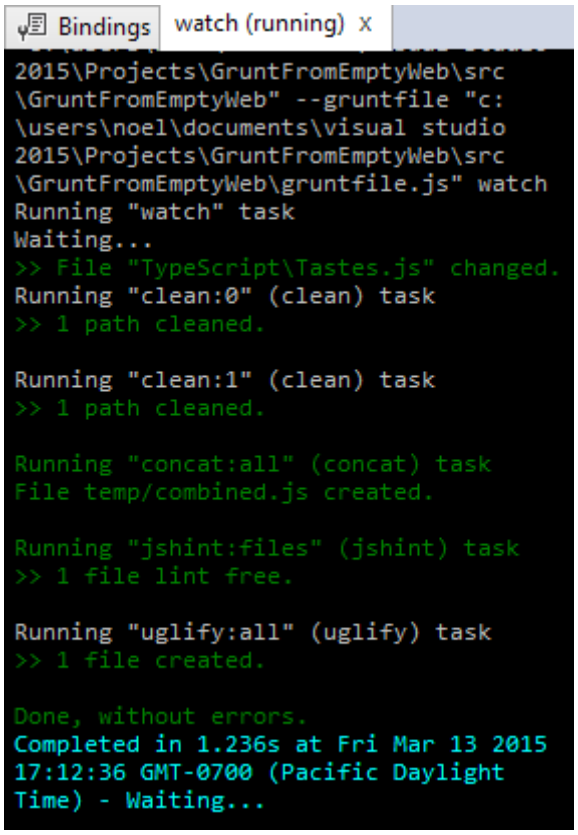
```
grunt.registerTask("all", ['clean', 'concat', 'jshint', 'uglify']);
```

The new task shows up in Task Runner Explorer under Alias Tasks. You can right-click and run it just as you would other tasks. The `all` task will run `clean`, `concat`, `jshint` and `uglify`, in order.

Watching for changes

A `watch` task keeps an eye on files and directories. The watch triggers tasks automatically if it detects changes. Add the code below to initConfig to watch for changes to *.js files in the TypeScript directory. If a JavaScript file is changed, `watch` will run the `all` task.

JavaScript

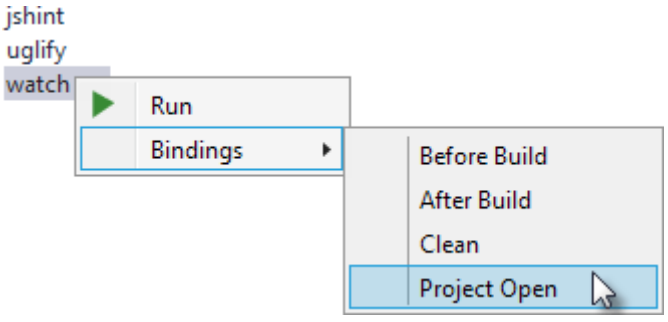


```
watch: {
  files: ["TypeScript/*.js"],
  tasks: ["all"]
}
```

Add a call to `loadNpmTasks()` to show the `watch` task in Task Runner Explorer.

JavaScript

```
grunt.loadNpmTasks('grunt-contrib-watch');
```



Right-click the watch task in Task Runner Explorer and select Run from the context menu. The command window that shows the watch task running will display a "Waiting..." message. Open one of the TypeScript files, add a space, and then save the file. This will trigger the watch task and trigger the other tasks to run in order. The screenshot below shows a sample run.

Binding to Visual Studio events

Unless you want to manually start your tasks every time you work in Visual Studio, bind tasks to **Before Build**, **After Build**, **Clean**, and **Project Open** events.

Bind `watch` so that it runs every time Visual Studio opens. In Task Runner Explorer, right-click the watch task and select **Bindings** > **Project Open** from the context menu.

Unload and reload the project. When the project loads again, the watch task starts running automatically.

Summary

Grunt is a powerful task runner that can be used to automate most client-build tasks. Grunt leverages NPM to deliver its packages, and features tooling integration with Visual Studio. Visual Studio's Task Runner Explorer detects changes to configuration files

and provides a convenient interface to run tasks, view running tasks, and bind tasks to Visual Studio events.

Bundle and minify static assets in ASP.NET Core

Article • 08/08/2024

By Scott Addie and David Pine

This article explains the benefits of applying bundling and minification, including how these features can be used with ASP.NET Core web apps.

What is bundling and minification

Bundling and minification are two distinct performance optimizations you can apply in a web app. Used together, bundling and minification improve performance by reducing the number of server requests and reducing the size of the requested static assets.

Bundling and minification primarily improve the first page request load time. Once a web page has been requested, the browser caches the static assets (JavaScript, CSS, and images). So, bundling and minification don't improve performance when requesting the same page, or pages, on the same site requesting the same assets. If the expires header isn't set correctly on the assets and if bundling and minification aren't used, the browser's freshness heuristics mark the assets stale after a few days. Additionally, the browser requires a validation request for each asset. In this case, bundling and minification provide a performance improvement even after the first page request.

Bundling

Bundling combines multiple files into a single file. Bundling reduces the number of server requests that are necessary to render a web asset, such as a web page. You can create any number of individual bundles specifically for CSS, JavaScript, etc. Fewer files mean fewer HTTP requests from the browser to the server or from the service providing your application. This results in improved first page load performance.

Minification

Minification removes unnecessary characters from code without altering functionality. The result is a significant size reduction in requested assets (such as CSS, images, and JavaScript files). Common side effects of minification include shortening variable names to one character and removing comments and unnecessary whitespace.

Consider the following JavaScript function:

```JavaScript
AddAltToImg = function (imageTagAndImageID, imageContext) {
  ///<signature>
  ///<summary> Adds an alt tab to the image
  // </summary>
  //<param name="imgElement" type="String">The image selector.</param>
  //<param name="ContextForImage" type="String">The image context.</param>
  ///</signature>
  var imageElement = $(imageTagAndImageID, imageContext);
  imageElement.attr('alt', imageElement.attr('id').replace(/ID/, ''));
}
```

Minification reduces the function to the following:

```JavaScript
AddAltToImg=function(t,a){var
r=$(t,a);r.attr("alt",r.attr("id").replace(/ID/,""))};
```

In addition to removing the comments and unnecessary whitespace, the following parameter and variable names were renamed as follows:

Expand table

Original	Renamed
`imageTagAndImageID`	`t`
`imageContext`	`a`
`imageElement`	`r`

Impact of bundling and minification

The following table outlines differences between individually loading assets and using bundling and minification for a typical web app.

Expand table

Action	Without B/M	With B/M	Reduction
File Requests	18	7	61%

Action	Without B/M	With B/M	Reduction
Bytes Transferred (KB)	265	156	41%
Load Time (ms)	2360	885	63%

The load time improved, but this example ran locally. Greater performance gains are realized when using bundling and minification with assets transferred over a network.

The test app used to generate the figures in the preceding table demonstrates typical improvements that might not apply to a given app. We recommend testing an app to determine if bundling and minification yields an improved load time.

Choose a bundling and minification strategy

ASP.NET Core is compatible with WebOptimizer, an open-source bundling and minification solution. For set up instructions and sample projects, see WebOptimizer. ASP.NET Core doesn't provide a native bundling and minification solution.

Third-party tools, such as Gulp and Webpack, provide workflow automation for bundling and minification, as well as linting and image optimization. By using bundling and minification, the minified files are created prior to the app's deployment. Bundling and minifying before deployment provides the advantage of reduced server load. However, it's important to recognize that bundling and minification increases build complexity and only works with static files.

Environment-based bundling and minification

As a best practice, the bundled and minified files of your app should be used in a production environment. During development, the original files make for easier debugging of the app.

Specify which files to include in your pages by using the Environment Tag Helper in your views. The Environment Tag Helper only renders its contents when running in specific environments.

The following `environment` tag renders the unprocessed CSS files when running in the `Development` environment:

CSHTML

```
<environment include="Development">
    <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css" />
```

```
    <link rel="stylesheet" href="~/css/site.css" />
</environment>
```

The following `environment` tag renders the bundled and minified CSS files when running in an environment other than `Development`. For example, running in `Production` or `Staging` triggers the rendering of these stylesheets:

CSHTML

```
<environment exclude="Development">
    <link rel="stylesheet"
href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
          asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
          asp-fallback-test-class="sr-only" asp-fallback-test-
property="position" asp-fallback-test-value="absolute" />
    <link rel="stylesheet" href="~/css/site.min.css" asp-append-
version="true" />
</environment>
```

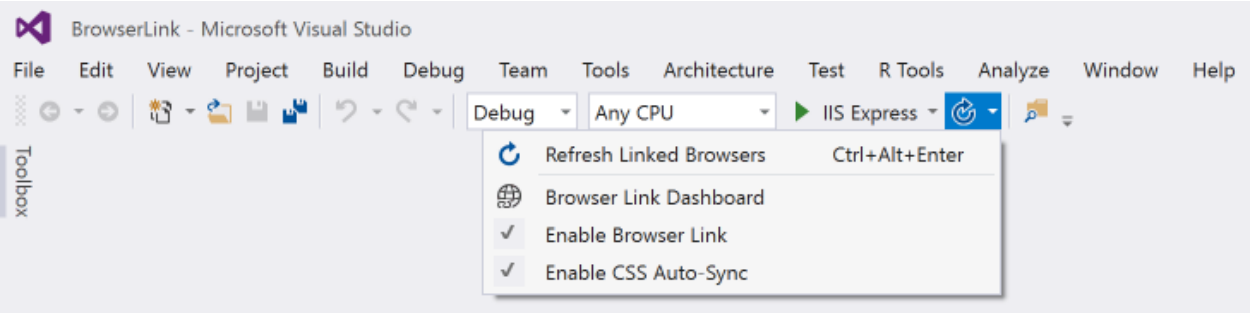
Browser link in ASP.NET Core

Article • 06/17/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Nicolò Carandini and Tom Dykstra

Browser link is a Visual Studio feature. It creates a communication channel between the development environment and one or more web browsers. Use browser link to:



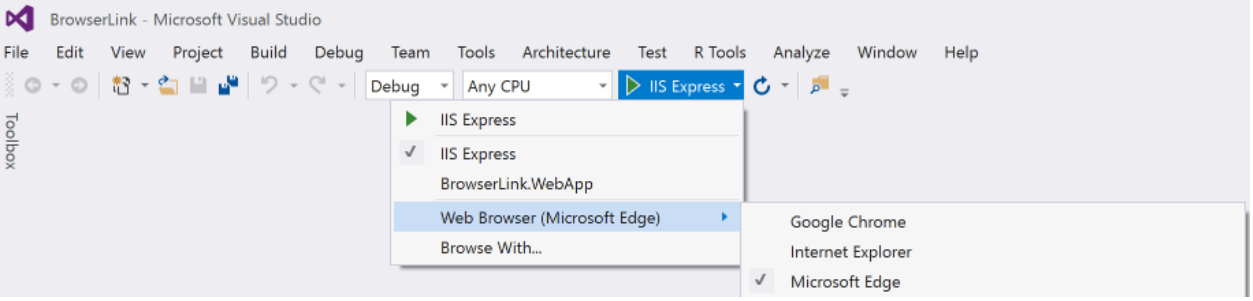
- Refresh your web app in several browsers at once.
- Test across multiple browsers with specific settings such as screen sizes.
- Select UI elements in browsers in real-time, see what markup and source it's correlated to in Visual Studio.
- Conduct real-time browser test automation.

Runtime compilation vs. hot reload

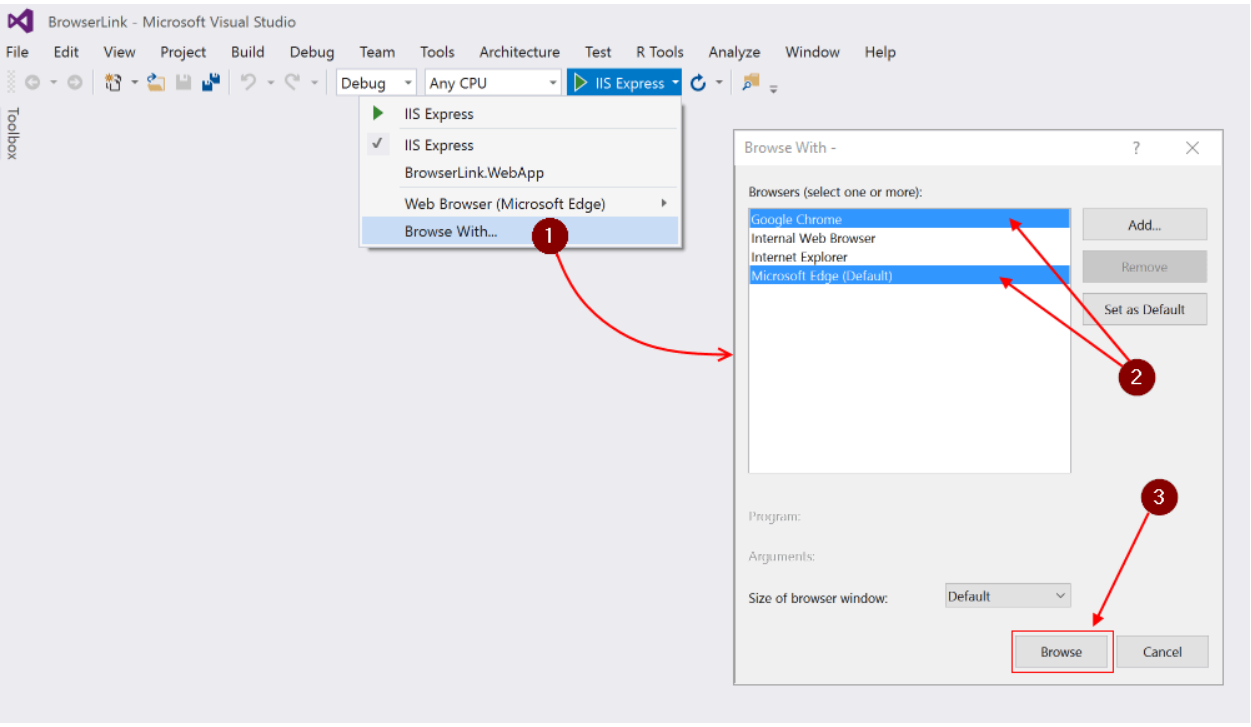
Use browser Link with runtime compilation or hot reload to see the effect of run-time changes in Razor (`.cshtml`) files. We recommend hot reload.

How to use browser link

When you have an ASP.NET Core project open, Visual Studio shows the browser link toolbar control next to the **Debug Type** toolbar control:

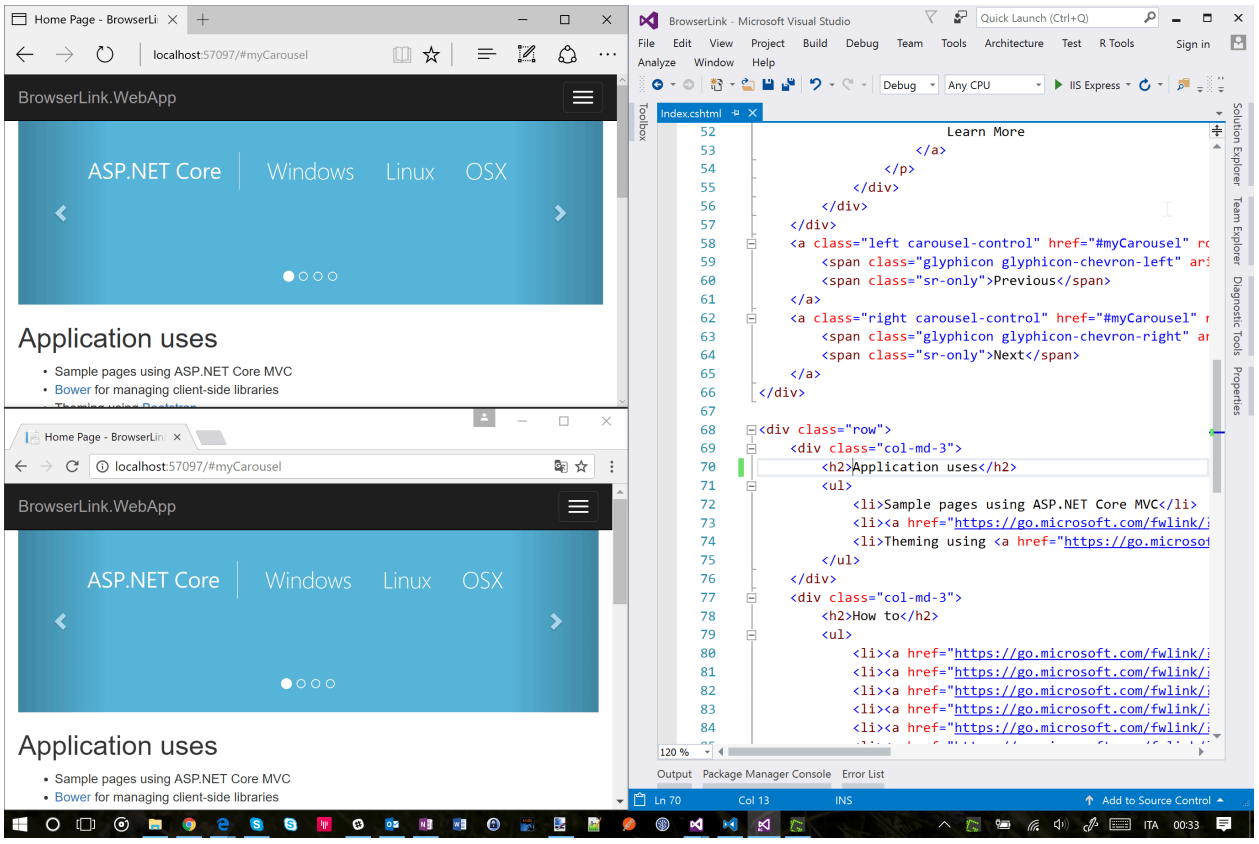


From the browser link toolbar control, you can:

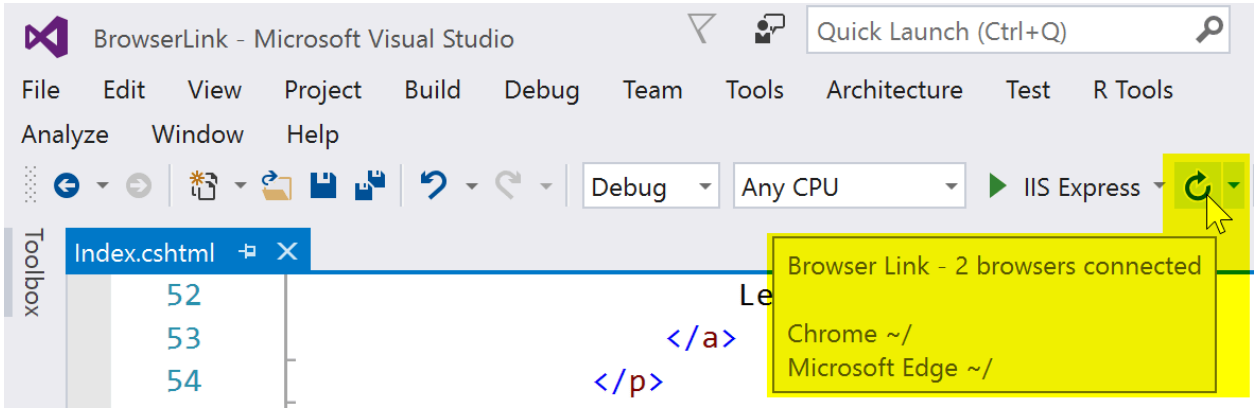


- Refresh the web app in several browsers at once.
- Open the **Browser Link Dashboard**.
- Enable or disable **Browser Link**.
- Enable or disable **CSS Hot Reload**.

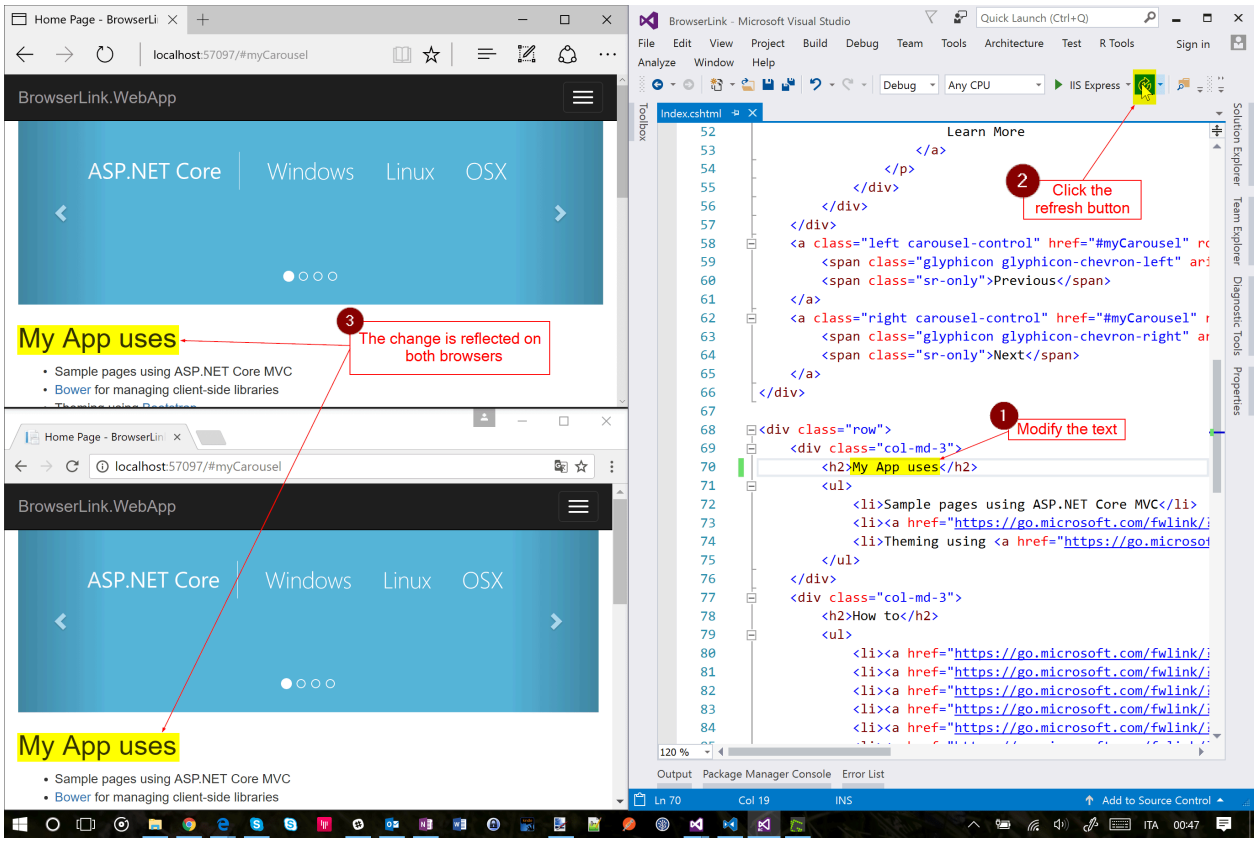
Refresh the web app in several browsers at once



To choose a single web browser to launch when starting the project, use the drop-down menu in the **Debug Target** toolbar control:

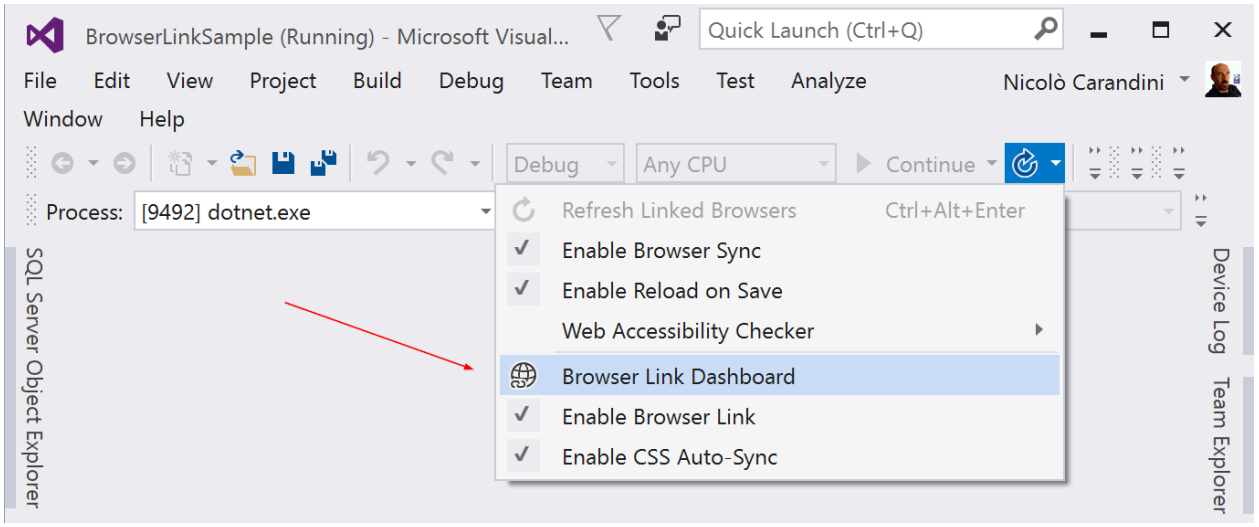


To open multiple browsers at once, choose **Browse with...** from the same drop-down. Hold down the `Ctrl` key to select the browsers you want, and then click **Browse**:

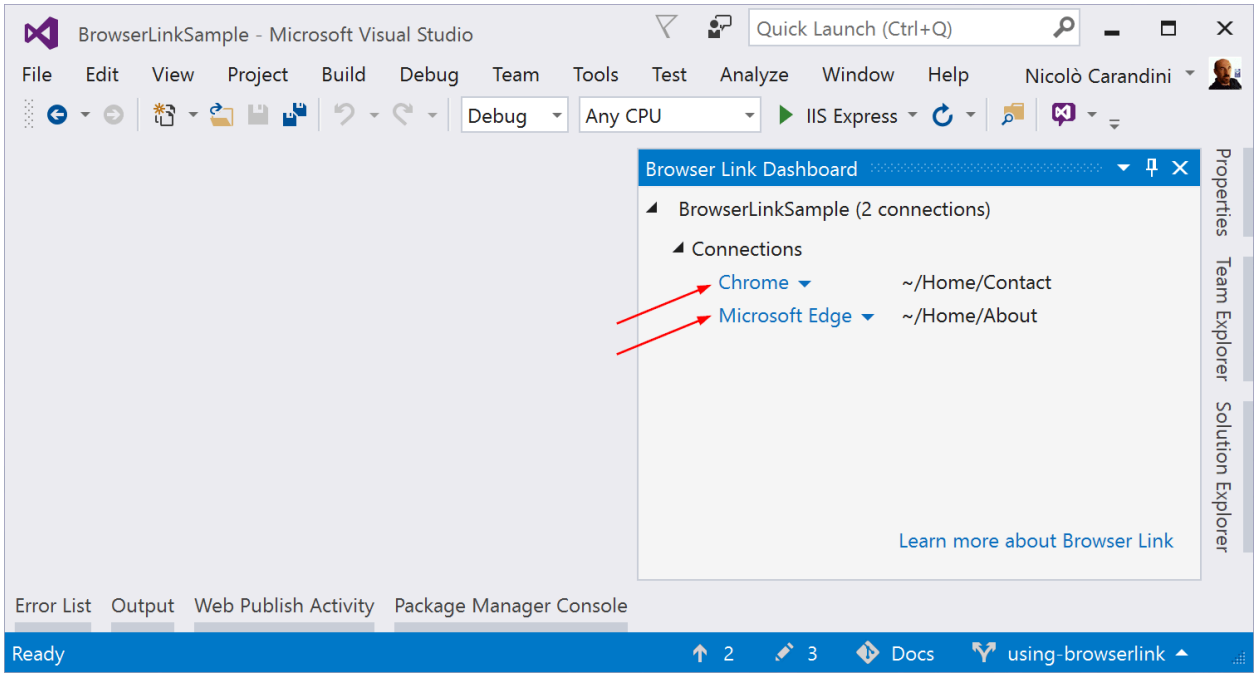


The following screenshot shows Visual Studio with the Index view open and two open browsers:

Hover over the browser link toolbar control to see the browsers that are connected to the project:



Change the Index view, and all connected browsers are updated when you click the browser link refresh button:



browser link also works with browsers that you launch from outside Visual Studio and navigate to the app URL.

The browser link dashboard

Open the **browser link dashboard** window from the browser link drop down menu to manage the connection with open browsers:

The connected browsers are shown with the path to the page that each browser is showing:

You can also click on an individual browser name to refresh only that browser.

Enable or disable browser link

When you re-enable browser link after disabling it, you must refresh the browsers to reconnect them.

Enable or disable CSS hot reload

When CSS hot reload is enabled, connected browsers are automatically refreshed when you make any change to CSS files.

How it works

browser link uses SignalR to create a communication channel between Visual Studio and the browser. When browser link is enabled, Visual Studio acts as a SignalR server that multiple clients (browsers) can connect to. browser link also registers a middleware component in the ASP.NET Core request pipeline. This component injects special `<script>` references into every page request from the server. You can see the script references by selecting **View source** in the browser and scrolling to the end of the `<body>` tag content:

HTML

```
    <!-- Visual Studio browser link -->
    <script type="application/json" id="__browserLink_initializationData">
```

```
{"requestId":"a717d5a07c1741949a7cefd6fa2bad08","requestMappingFromServer":f
alse}
    </script>
    <script type="text/javascript"
src="http://localhost:54139/b6e36e429d034f578ebccd6a79bf19bf/browserLink"
async="async"></script>
    <!-- End browser link -->
</body>
```

Your source files aren't modified. The middleware component injects the script references dynamically.

Because the browser-side code is all JavaScript, it works on all browsers that SignalR supports without requiring a browser plug-in.

Session and state management in ASP.NET Core

Article • 09/18/2024

By Rick Anderson, Kirk Larkin, and Diana LaRose

HTTP is a stateless protocol. By default, HTTP requests are independent messages that don't retain user values. This article describes several approaches to preserve user data between requests.

For Blazor state management guidance, which adds to or supersedes the guidance in this article, see ASP.NET Core Blazor state management.

State management

State can be stored using several approaches. Each approach is described later in this article.

Expand table

Storage approach	Storage mechanism
Cookies	HTTP cookies. May include data stored using server-side app code.
Session state	HTTP cookies and server-side app code
TempData	HTTP cookies or session state
Query strings	HTTP query strings
Hidden fields	HTTP form fields
HttpContext.Items	Server-side app code
Cache	Server-side app code

SignalR/Blazor Server and HTTP context-based state management

SignalR apps shouldn't use session state and other state management approaches that rely upon a stable HTTP context to store information. SignalR apps can store per-connection state in Context.Items in the hub. For more information and alternative state

management approaches for Blazor Server apps, see ASP.NET Core Blazor state management.

Cookies

Cookies store data across requests. Because cookies are sent with every request, their size should be kept to a minimum. Ideally, only an identifier should be stored in a cookie with the data stored by the app. Most browsers restrict cookie size to 4096 bytes. Only a limited number of cookies are available for each domain.

Because cookies are subject to tampering, they must be validated by the app. Cookies can be deleted by users and expire on clients. However, cookies are generally the most durable form of data persistence on the client.

Cookies are often used for personalization, where content is customized for a known user. The user is only identified and not authenticated in most cases. The cookie can store the user's name, account name, or unique user ID such as a GUID. The cookie can be used to access the user's personalized settings, such as their preferred website background color.

See the European Union General Data Protection Regulations (GDPR) when issuing cookies and dealing with privacy concerns. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.

Session state

Session state is an ASP.NET Core scenario for storage of user data while the user browses a web app. Session state uses a store maintained by the app to persist data across requests from a client. The session data is backed by a cache and considered ephemeral data. The site should continue to function without the session data. Critical application data should be stored in the user database and cached in session only as a performance optimization.

Session isn't supported in SignalR apps because a SignalR Hub may execute independent of an HTTP context. For example, this can occur when a long polling request is held open by a hub beyond the lifetime of the request's HTTP context.

ASP.NET Core maintains session state by providing a cookie to the client that contains a session ID. The cookie session ID:

- Is sent to the app with each request.
- Is used by the app to fetch the session data.

Session state exhibits the following behaviors:

- The session cookie is specific to the browser. Sessions aren't shared across browsers.
- Session cookies are deleted when the browser session ends.
- If a cookie is received for an expired session, a new session is created that uses the same session cookie.
- Empty sessions aren't retained. The session must have at least one value set to persist the session across requests. When a session isn't retained, a new session ID is generated for each new request.
- The app retains a session for a limited time after the last request. The app either sets the session timeout or uses the default value of 20 minutes. Session state is ideal for storing user data:
  - That's specific to a particular session.
  - Where the data doesn't require permanent storage across sessions.
- Session data is deleted either when the ISession.Clear implementation is called or when the session expires.
- There's no default mechanism to inform app code that a client browser has been closed or when the session cookie is deleted or expired on the client.
- Session state cookies aren't marked essential by default. Session state isn't functional unless tracking is permitted by the site visitor. For more information, see General Data Protection Regulation (GDPR) support in ASP.NET Core.
- **Note**: There is no replacement for the cookieless session feature from the ASP.NET Framework because it's considered insecure and can lead to session fixation attacks.

> ⚠ **Warning**
>
> Don't store sensitive data in session state. The user might not close the browser and clear the session cookie. Some browsers maintain valid session cookies across browser windows. A session might not be restricted to a single user. The next user might continue to browse the app with the same session cookie.

The in-memory cache provider stores session data in the memory of the server where the app resides. In a server farm scenario:

- Use *sticky sessions* to tie each session to a specific app instance on an individual server. Azure App Service uses Application Request Routing (ARR) to enforce sticky sessions by default. However, sticky sessions can affect scalability and complicate web app updates. A better approach is to use a Redis or SQL Server

distributed cache, which doesn't require sticky sessions. For more information, see Distributed caching in ASP.NET Core.

- The session cookie is encrypted via IDataProtector. Data Protection must be properly configured to read session cookies on each machine. For more information, see ASP.NET Core Data Protection Overview and Key storage providers.

Configure session state

Middleware for managing session state is included in the framework. To enable the session middleware, `Program.cs` must contain:

- Any of the IDistributedCache memory caches. The `IDistributedCache` implementation is used as a backing store for session. For more information, see Distributed caching in ASP.NET Core.
- A call to AddSession
- A call to UseSession

The following code shows how to set up the in-memory session provider with a default in-memory implementation of `IDistributedCache`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddDistributedMemoryCache();

builder.Services.AddSession(options =>
{
    options.IdleTimeout = TimeSpan.FromSeconds(10);
    options.Cookie.HttpOnly = true;
    options.Cookie.IsEssential = true;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();
```

```
app.UseRouting();

app.UseAuthorization();

app.UseSession();

app.MapRazorPages();
app.MapDefaultControllerRoute();

app.Run();
```

The preceding code sets a short timeout to simplify testing.

The order of middleware is important. Call `UseSession` after `UseRouting` and before `MapRazorPages` and `MapDefaultControllerRoute` . See Middleware Ordering.

HttpContext.Session is available after session state is configured.

`HttpContext.Session` can't be accessed before `UseSession` has been called.

A new session with a new session cookie can't be created after the app has begun writing to the response stream. The exception is recorded in the web server log and not displayed in the browser.

Load session state asynchronously

The default session provider in ASP.NET Core loads session records from the underlying IDistributedCache backing store asynchronously only if the ISession.LoadAsync method is explicitly called before the TryGetValue, Set, or Remove methods. If `LoadAsync` isn't called first, the underlying session record is loaded synchronously, which can incur a performance penalty at scale.

To have apps enforce this pattern, wrap the DistributedSessionStore and DistributedSession implementations with versions that throw an exception if the `LoadAsync` method isn't called before `TryGetValue`, `Set`, or `Remove`. Register the wrapped versions in the services container.

Session options

To override session defaults, use SessionOptions.

Expand table

Option	Description
Cookie	Determines the settings used to create the cookie. Name defaults to SessionDefaults.CookieName (`.AspNetCore.Session`). Path defaults to SessionDefaults.CookiePath (`/`). SameSite defaults to SameSiteMode.Lax (`1`). HttpOnly defaults to `true`. IsEssential defaults to `false`.
IdleTimeout	The `IdleTimeout` indicates how long the session can be idle before its contents are abandoned. Each session access resets the timeout. This setting only applies to the content of the session, not the cookie. The default is 20 minutes.
IOTimeout	The maximum amount of time allowed to load a session from the store or to commit it back to the store. This setting may only apply to asynchronous operations. This timeout can be disabled using InfiniteTimeSpan. The default is 1 minute.

Session uses a cookie to track and identify requests from a single browser. By default, this cookie is named `.AspNetCore.Session`, and it uses a path of `/`. Because the cookie default doesn't specify a domain, it isn't made available to the client-side script on the page (because HttpOnly defaults to `true`).

To override cookie session defaults, use SessionOptions:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages();
builder.Services.AddControllersWithViews();

builder.Services.AddDistributedMemoryCache();

builder.Services.AddSession(options =>
{
    options.Cookie.Name = ".AdventureWorks.Session";
    options.IdleTimeout = TimeSpan.FromSeconds(10);
    options.Cookie.IsEssential = true;
});

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();
```

```
app.UseAuthorization();

app.UseSession();

app.MapRazorPages();
app.MapDefaultControllerRoute();

app.Run();
```

The app uses the IdleTimeout property to determine how long a session can be idle before its contents in the server's cache are abandoned. This property is independent of the cookie expiration. Each request that passes through the Session Middleware resets the timeout.

Session state is *non-locking*. If two requests simultaneously attempt to modify the contents of a session, the last request overrides the first. `Session` is implemented as a *coherent session*, which means that all the contents are stored together. When two requests seek to modify different session values, the last request may override session changes made by the first.

Set and get Session values

Session state is accessed from a Razor Pages PageModel class or MVC Controller class with HttpContext.Session. This property is an ISession implementation.

The `ISession` implementation provides several extension methods to set and retrieve integer and string values. The extension methods are in the Microsoft.AspNetCore.Http namespace.

`ISession` extension methods:

- Get(ISession, String)
- GetInt32(ISession, String)
- GetString(ISession, String)
- SetInt32(ISession, String, Int32)
- SetString(ISession, String, String)

The following example retrieves the session value for the `IndexModel.SessionKeyName` key (`_Name` in the sample app) in a Razor Pages page:

C#

```
@page
@using Microsoft.AspNetCore.Http
```

```
@model IndexModel

...

Name: @HttpContext.Session.GetString(IndexModel.SessionKeyName)
```

The following example shows how to set and get an integer and a string:

C#

```
public class IndexModel : PageModel
{
    public const string SessionKeyName = "_Name";
    public const string SessionKeyAge = "_Age";

    private readonly ILogger<IndexModel> _logger;

    public IndexModel(ILogger<IndexModel> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {
        if
(string.IsNullOrEmpty(HttpContext.Session.GetString(SessionKeyName)))
        {
            HttpContext.Session.SetString(SessionKeyName, "The Doctor");
            HttpContext.Session.SetInt32(SessionKeyAge, 73);
        }
        var name = HttpContext.Session.GetString(SessionKeyName);
        var age = HttpContext.Session.GetInt32(SessionKeyAge).ToString();

        _logger.LogInformation("Session Name: {Name}", name);
        _logger.LogInformation("Session Age: {Age}", age);
    }
}
```

The following markup displays the session values on a Razor Page:

CSHTML

```
@page
@model PrivacyModel
@{
    ViewData["Title"] = "Privacy Policy";
}
<h1>@ViewData["Title"]</h1>

<div class="text-center">
<p><b>Name:</b> @HttpContext.Session.GetString("_Name");<b>Age:
```

```
</b> @HttpContext.Session.GetInt32("_Age").ToString()</p>
</div>
```

All session data must be serialized to enable a distributed cache scenario, even when using the in-memory cache. String and integer serializers are provided by the extension methods of ISession. Complex types must be serialized by the user using another mechanism, such as JSON.

Use the following sample code to serialize objects:

C#

```
public static class SessionExtensions
{
    public static void Set<T>(this ISession session, string key, T value)
    {
        session.SetString(key, JsonSerializer.Serialize(value));
    }

    public static T? Get<T>(this ISession session, string key)
    {
        var value = session.GetString(key);
        return value == null ? default : JsonSerializer.Deserialize<T>
(value);
    }
}
```

The following example shows how to set and get a serializable object with the `SessionExtensions` class:

C#

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using Web.Extensions;    // SessionExtensions

namespace SessionSample.Pages
{
    public class Index6Model : PageModel
    {
        const string SessionKeyTime = "_Time";
        public string? SessionInfo_SessionTime { get; private set; }
        private readonly ILogger<Index6Model> _logger;

        public Index6Model(ILogger<Index6Model> logger)
        {
            _logger = logger;
        }
```

```
        public void OnGet()
        {
            var currentTime = DateTime.Now;

            // Requires SessionExtensions from sample.
            if (HttpContext.Session.Get<DateTime>(SessionKeyTime) ==
default)
            {
                HttpContext.Session.Set<DateTime>(SessionKeyTime,
currentTime);
            }
            _logger.LogInformation("Current Time: {Time}", currentTime);
            _logger.LogInformation("Session Time: {Time}",
                                   HttpContext.Session.Get<DateTime>
(SessionKeyTime));

        }
    }
}
```

> ⚠ **Warning**
>
> Storing a live object in the session should be used with caution, as there are many problems that can occur with serialized objects. For more information, see Sessions should be allowed to store objects (dotnet/aspnetcore #18159).

TempData

ASP.NET Core exposes the Razor Pages TempData or Controller TempData. This property stores data until it's read in another request. The Keep(String) and Peek(string) methods can be used to examine the data without deletion at the end of the request. Keep marks all items in the dictionary for retention. `TempData` is:

- Useful for redirection when data is required for more than a single request.
- Implemented by `TempData` providers using either cookies or session state.

TempData samples

Consider the following page that creates a customer:

C#

```
public class CreateModel : PageModel
{
    private readonly RazorPagesContactsContext _context;
```

```
    public CreateModel(RazorPagesContactsContext context)
    {
        _context = context;
    }

    public IActionResult OnGet()
    {
        return Page();
    }

    [TempData]
    public string Message { get; set; }

    [BindProperty]
    public Customer Customer { get; set; }

    public async Task<IActionResult> OnPostAsync()
    {
        if (!ModelState.IsValid)
        {
            return Page();
        }

        _context.Customer.Add(Customer);
        await _context.SaveChangesAsync();
        Message = $"Customer {Customer.Name} added";

        return RedirectToPage("./IndexPeek");
    }
}
```

The following page displays `TempData["Message"]`:

CSHTML

```
@page
@model IndexModel

<h1>Peek Contacts</h1>

@{
    if (TempData.Peek("Message") != null)
    {
        <h3>Message: @TempData.Peek("Message")</h3>
    }
}

@*Content removed for brevity.*@
```

In the preceding markup, at the end of the request, `TempData["Message"]` is **not** deleted because `Peek` is used. Refreshing the page displays the contents of `TempData["Message"]`.

The following markup is similar to the preceding code, but uses `Keep` to preserve the data at the end of the request:

CSHTML

```
@page
@model IndexModel

<h1>Contacts Keep</h1>

@{
    if (TempData["Message"] != null)
    {
        <h3>Message: @TempData["Message"]</h3>
    }
    TempData.Keep("Message");
}

@*Content removed for brevity.*@
```

Navigating between the *IndexPeek* and *IndexKeep* pages won't delete `TempData["Message"]`.

The following code displays `TempData["Message"]`, but at the end of the request, `TempData["Message"]` is deleted:

CSHTML

```
@page
@model IndexModel

<h1>Index no Keep or Peek</h1>

@{
    if (TempData["Message"] != null)
    {
        <h3>Message: @TempData["Message"]</h3>
    }
}

@*Content removed for brevity.*@
```

TempData providers

The cookie-based TempData provider is used by default to store TempData in cookies.

The cookie data is encrypted using IDataProtector, encoded with Base64UrlTextEncoder, then chunked. The maximum cookie size is less than 4096 bytes due to encryption and chunking. The cookie data isn't compressed because compressing encrypted data can lead to security problems such as the CRIME and BREACH attacks. For more information on the cookie-based TempData provider, see CookieTempDataProvider.

Choose a TempData provider

Choosing a TempData provider involves several considerations, such as:

- Does the app already use session state? If so, using the session state TempData provider has no additional cost to the app beyond the size of the data.
- Does the app use TempData only sparingly for relatively small amounts of data, up to 500 bytes? If so, the cookie TempData provider adds a small cost to each request that carries TempData. If not, the session state TempData provider can be beneficial to avoid round-tripping a large amount of data in each request until the TempData is consumed.
- Does the app run in a server farm on multiple servers? If so, there's no additional configuration required to use the cookie TempData provider outside of Data Protection. For more information, see ASP.NET Core Data Protection Overview and Key storage providers.

Most web clients such as web browsers enforce limits on the maximum size of each cookie and the total number of cookies. When using the cookie TempData provider, verify the app won't exceed these limits. Consider the total size of the data. Account for increases in cookie size due to encryption and chunking.

Configure the TempData provider

The cookie-based TempData provider is enabled by default.

To enable the session-based TempData provider, use the AddSessionStateTempDataProvider extension method. Only one call to `AddSessionStateTempDataProvider` is required:

```
C#

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddRazorPages()
                    .AddSessionStateTempDataProvider();
builder.Services.AddControllersWithViews()
                    .AddSessionStateTempDataProvider();

builder.Services.AddSession();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.UseSession();

app.MapRazorPages();
app.MapDefaultControllerRoute();

app.Run();
```

Query strings

A limited amount of data can be passed from one request to another by adding it to the new request's query string. This is useful for capturing state in a persistent manner that allows links with embedded state to be shared through email or social networks. Because URL query strings are public, never use query strings for sensitive data.

In addition to unintended sharing, including data in query strings can expose the app to Cross-Site Request Forgery (CSRF) attacks. Any preserved session state must protect against CSRF attacks. For more information, see Prevent Cross-Site Request Forgery (XSRF/CSRF) attacks in ASP.NET Core.

Hidden fields

Data can be saved in hidden form fields and posted back on the next request. This is common in multi-page forms. Because the client can potentially tamper with the data, the app must always revalidate the data stored in hidden fields.

`HttpContext.Items`

The HttpContext.Items collection is used to store data while processing a single request. The collection's contents are discarded after a request is processed. The `Items` collection is often used to allow components or middleware to communicate when they operate at different points in time during a request and have no direct way to pass parameters.

In the following example, middleware adds `isVerified` to the `Items` collection:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

ILogger logger = app.Logger;

app.Use(async (context, next) =>
{
    // context.Items["isVerified"] is null
    logger.LogInformation($"Before setting: Verified:
{context.Items["isVerified"]}");
    context.Items["isVerified"] = true;
    await next.Invoke();
});

app.Use(async (context, next) =>
{
    // context.Items["isVerified"] is true
    logger.LogInformation($"Next: Verified: {context.Items["isVerified"]}");
    await next.Invoke();
});

app.MapGet("/", async context =>
{
    await context.Response.WriteAsync($"Verified:
{context.Items["isVerified"]}");
});

app.Run();
```

For middleware that's only used in a single app, it's unlikely that using a fixed `string` key would cause a key collision. However, to avoid the possibility of a key collision altogether, an `object` can be used as an item key. This approach is particularly useful for middleware that's shared between apps and also has the advantage of eliminating the use of key strings in the code. The following example shows how to use an `object` key defined in a middleware class:

C#

```
public class HttpContextItemsMiddleware
{
    private readonly RequestDelegate _next;
    public static readonly object HttpContextItemsMiddlewareKey = new();

    public HttpContextItemsMiddleware(RequestDelegate next)
    {
        _next = next;
    }

    public async Task Invoke(HttpContext httpContext)
    {
        httpContext.Items[HttpContextItemsMiddlewareKey] = "K-9";

        await _next(httpContext);
    }
}

public static class HttpContextItemsMiddlewareExtensions
{
    public static IApplicationBuilder
        UseHttpContextItemsMiddleware(this IApplicationBuilder app)
    {
        return app.UseMiddleware<HttpContextItemsMiddleware>();
    }
}
```

Other code can access the value stored in `HttpContext.Items` using the key exposed by the middleware class:

C#

```
public class Index2Model : PageModel
{
    private readonly ILogger<Index2Model> _logger;

    public Index2Model(ILogger<Index2Model> logger)
    {
        _logger = logger;
    }

    public void OnGet()
    {
        HttpContext.Items

.TryGetValue(HttpContextItemsMiddleware.HttpContextItemsMiddlewareKey,
                out var middlewareSetValue);

        _logger.LogInformation("Middleware value {MV}",
            middlewareSetValue?.ToString() ?? "Middleware value not set!");
```

```
    }
}
```

Cache

Caching is an efficient way to store and retrieve data. The app can control the lifetime of cached items. For more information, see Response caching in ASP.NET Core.

Cached data isn't associated with a specific request, user, or session. **Do not cache user-specific data that may be retrieved by other user requests.**

To cache application wide data, see Cache in-memory in ASP.NET Core.

Checking session state

ISession.IsAvailable is intended to check for transient failures. Calling `IsAvailable` before the session middleware runs throws an `InvalidOperationException`.

Libraries that need to test session availability can use `HttpContext.Features.Get<ISessionFeature>()?.Session != null`.

Common errors

- "Unable to resolve service for type 'Microsoft.Extensions.Caching.Distributed.IDistributedCache' while attempting to activate 'Microsoft.AspNetCore.Session.DistributedSessionStore'."

  This is typically caused by failing to configure at least one `IDistributedCache` implementation. For more information, see Distributed caching in ASP.NET Core and Cache in-memory in ASP.NET Core.

If the session middleware fails to persist a session:

- The middleware logs the exception and the request continues normally.
- This leads to unpredictable behavior.

The session middleware can fail to persist a session if the backing store isn't available. For example, a user stores a shopping cart in session. The user adds an item to the cart but the commit fails. The app doesn't know about the failure so it reports to the user that the item was added to their cart, which isn't true.

The recommended approach to check for errors is to call `await feature.Session.CommitAsync` when the app is done writing to the session. CommitAsync throws an exception if the backing store is unavailable. If `CommitAsync` fails, the app can process the exception. LoadAsync throws under the same conditions when the data store is unavailable.

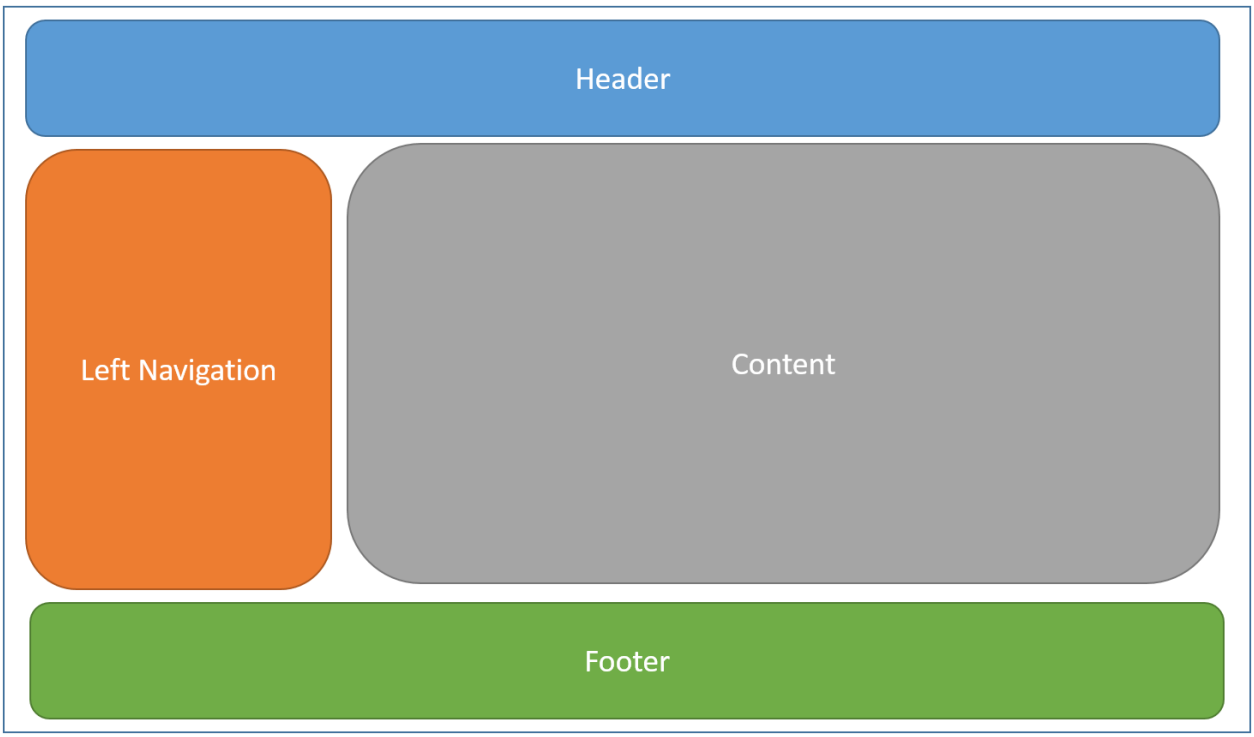
Layout in ASP.NET Core

Article • 06/03/2022

By Steve Smith and Dave Brock

Pages and views frequently share visual and programmatic elements. This article demonstrates how to:

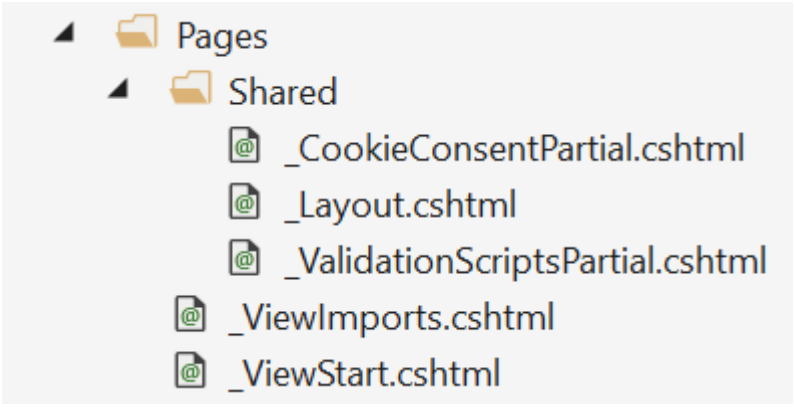


- Use common layouts.
- Share directives.
- Run common code before rendering pages or views.

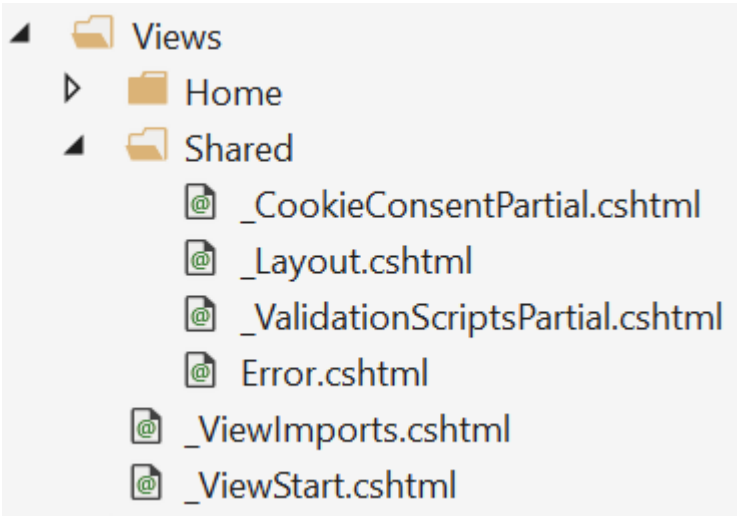
This document discusses layouts for the two different approaches to ASP.NET Core MVC: Razor Pages and controllers with views. For this topic, the differences are minimal:

- Razor Pages are in the *Pages* folder.
- Controllers with views uses a *Views* folder for views.

What is a Layout



Most web apps have a common layout that provides the user with a consistent experience as they navigate from page to page. The layout typically includes common user interface elements such as the app header, navigation or menu elements, and footer.



Common HTML structures such as scripts and stylesheets are also frequently used by many pages within an app. All of these shared elements may be defined in a *layout* file, which can then be referenced by any view used within the app. Layouts reduce duplicate code in views.

By convention, the default layout for an ASP.NET Core app is named `_Layout.cshtml`. The layout files for new ASP.NET Core projects created with the templates are:

- Razor Pages: `Pages/Shared/_Layout.cshtml`

- Controller with views: `Views/Shared/_Layout.cshtml`

The layout defines a top level template for views in the app. Apps don't require a layout. Apps can define more than one layout, with different views specifying different layouts.

The following code shows the layout file for a template created project with a controller and views:

CSHTML

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
```

```
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebApplication1</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css"
/>
        <link rel="stylesheet" href="~/css/site.css" />
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet"
href="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/css/bootstrap.min.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.min.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-
property="position" asp-fallback-test-value="absolute" />
        <link rel="stylesheet" href="~/css/site.min.css" asp-append-
version="true" />
    </environment>
</head>
<body>
    <nav class="navbar navbar-inverse navbar-fixed-top">
        <div class="container">
            <div class="navbar-header">
                <button type="button" class="navbar-toggle" data-
toggle="collapse" data-target=".navbar-collapse">
                    <span class="sr-only">Toggle navigation</span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                    <span class="icon-bar"></span>
                </button>
                <a asp-page="/Index" class="navbar-
brand">WebApplication1</a>
            </div>
            <div class="navbar-collapse collapse">
                <ul class="nav navbar-nav">
                    <li><a asp-page="/Index">Home</a></li>
                    <li><a asp-page="/About">About</a></li>
                    <li><a asp-page="/Contact">Contact</a></li>
                </ul>
            </div>
        </div>
    </nav>

    <partial name="_CookieConsentPartial" />

    <div class="container body-content">
        @RenderBody()
        <hr />
        <footer>
            <p>&copy; 2018 - WebApplication1</p>
        </footer>
    </div>

    <environment include="Development">
        <script src="~/lib/jquery/dist/jquery.js"></script>
        <script src="~/lib/bootstrap/dist/js/bootstrap.js"></script>
```

```
        <script src="~/js/site.js" asp-append-version="true"></script>
    </environment>
    <environment exclude="Development">
        <script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-
3.3.1.min.js"
                asp-fallback-src="~/lib/jquery/dist/jquery.min.js"
                asp-fallback-test="window.jQuery"
                crossorigin="anonymous"
                integrity="sha384-
tsQFqpEReu7ZLhBV2VZlAu7zcOV+rXbYlF2cqB8txI/8aZajjp4Bqd+V6D5IgvKT">
        </script>
        <script
src="https://ajax.aspnetcdn.com/ajax/bootstrap/3.3.7/bootstrap.min.js"
                asp-fallback-src="~/lib/bootstrap/dist/js/bootstrap.min.js"
                asp-fallback-test="window.jQuery && window.jQuery.fn &&
window.jQuery.fn.modal"
                crossorigin="anonymous"
                integrity="sha384-
Tc5IQib027qvyjSMfHjOMaLkfuWVxZxUPnCJA7l2mCWNIpG9mGCD8wGNIcPD7Txa">
        </script>
        <script src="~/js/site.min.js" asp-append-version="true"></script>
    </environment>

    @RenderSection("Scripts", required: false)
</body>
</html>
```

Specifying a Layout

Razor views have a `Layout` property. Individual views specify a layout by setting this property:

CSHTML

```
@{
    Layout = "_Layout";
}
```

The layout specified can use a full path (for example, `/Pages/Shared/_Layout.cshtml` or `/Views/Shared/_Layout.cshtml`) or a partial name (example: `_Layout`). When a partial name is provided, the Razor view engine searches for the layout file using its standard discovery process. The folder where the handler method (or controller) exists is searched first, followed by the *Shared* folder. This discovery process is identical to the process used to discover partial views.

By default, every layout must call `RenderBody`. Wherever the call to `RenderBody` is placed, the contents of the view will be rendered.

Sections

A layout can optionally reference one or more *sections*, by calling `RenderSection`. Sections provide a way to organize where certain page elements should be placed. Each call to `RenderSection` can specify whether that section is required or optional:

HTML

```
<script type="text/javascript" src="~/scripts/global.js"></script>

@RenderSection("Scripts", required: false)
```

If a required section isn't found, an exception is thrown. Individual views specify the content to be rendered within a section using the `@section` Razor syntax. If a page or view defines a section, it must be rendered (or an error will occur).

An example `@section` definition in Razor Pages view:

HTML

```
@section Scripts {
     <script type="text/javascript" src="~/scripts/main.js"></script>
}
```

In the preceding code, `scripts/main.js` is added to the `scripts` section on a page or view. Other pages or views in the same app might not require this script and wouldn't define a scripts section.

The following markup uses the Partial Tag Helper to render `_ValidationScriptsPartial.cshtml`:

HTML

```
@section Scripts {
    <partial name="_ValidationScriptsPartial" />
}
```

The preceding markup was generated by scaffolding Identity.

Sections defined in a page or view are available only in its immediate layout page. They cannot be referenced from partials, view components, or other parts of the view system.

Ignoring sections

By default, the body and all sections in a content page must all be rendered by the layout page. The Razor view engine enforces this by tracking whether the body and each section have been rendered.

To instruct the view engine to ignore the body or sections, call the `IgnoreBody` and `IgnoreSection` methods.

The body and every section in a Razor page must be either rendered or ignored.

Importing Shared Directives

Views and pages can use Razor directives to import namespaces and use dependency injection. Directives shared by many views may be specified in a common `_ViewImports.cshtml` file. The `_ViewImports` file supports the following directives:

- `@addTagHelper`
- `@removeTagHelper`
- `@tagHelperPrefix`
- `@using`
- `@model`
- `@inherits`
- `@inject`
- `@namespace`

The file doesn't support other Razor features, such as functions and section definitions.

A sample `_ViewImports.cshtml` file:

CSHTML

```
@using WebApplication1
@using WebApplication1.Models
@using WebApplication1.Models.AccountViewModels
@using WebApplication1.Models.ManageViewModels
@using Microsoft.AspNetCore.Identity
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The `_ViewImports.cshtml` file for an ASP.NET Core MVC app is typically placed in the *Pages* (or *Views*) folder. A `_ViewImports.cshtml` file can be placed within any folder, in which case it will only be applied to pages or views within that folder and its subfolders. `_ViewImports` files are processed starting at the root level and then for each folder

leading up to the location of the page or view itself. `_ViewImports` settings specified at the root level may be overridden at the folder level.

For example, suppose:

- The root level `_ViewImports.cshtml` file includes `@model MyModel1` and `@addTagHelper *, MyTagHelper1`.
- A subfolder `_ViewImports.cshtml` file includes `@model MyModel2` and `@addTagHelper *, MyTagHelper2`.

Pages and views in the subfolder will have access to both Tag Helpers and the `MyModel2` model.

If multiple `_ViewImports.cshtml` files are found in the file hierarchy, the combined behavior of the directives are:

- `@addTagHelper`, `@removeTagHelper`: all run, in order
- `@tagHelperPrefix`: the closest one to the view overrides any others
- `@model`: the closest one to the view overrides any others
- `@inherits`: the closest one to the view overrides any others
- `@using`: all are included; duplicates are ignored
- `@inject`: for each property, the closest one to the view overrides any others with the same property name

Running Code Before Each View

Code that needs to run before each view or page should be placed in the `_ViewStart.cshtml` file. By convention, the `_ViewStart.cshtml` file is located in the *Pages* (or *Views*) folder. The statements listed in `_ViewStart.cshtml` are run before every full view (not layouts, and not partial views). Like ViewImports.cshtml, `_ViewStart.cshtml` is hierarchical. If a `_ViewStart.cshtml` file is defined in the view or pages folder, it will be run after the one defined in the root of the *Pages* (or *Views*) folder (if any).

A sample `_ViewStart.cshtml` file:

CSHTML

```
@{
    Layout = "_Layout";
}
```

The file above specifies that all views will use the `_Layout.cshtml` layout.

`_ViewStart.cshtml` and `_ViewImports.cshtml` are **not** typically placed in the */Pages/Shared* (or */Views/Shared*) folder. The app-level versions of these files should be placed directly in the */Pages* (or */Views*) folder.

Razor syntax reference for ASP.NET Core

Article • 09/27/2024

By Rick Anderson, Taylor Mullen, and Dan Vicarel

Razor is a markup syntax for embedding .NET based code into webpages. The Razor syntax consists of Razor markup, C#, and HTML. Files containing Razor generally have a `.cshtml` file extension. Razor is also found in Razor component files (`.razor`). Razor syntax is similar to the templating engines of various JavaScript single-page application (SPA) frameworks, such as Angular, React, VueJs, and Svelte. For more information see, The features described in this article are obsolete as of ASP.NET Core 3.0.

Introduction to ASP.NET Web Programming Using the Razor Syntax provides many samples of programming with Razor syntax. Although the topic was written for ASP.NET rather than ASP.NET Core, most of the samples apply to ASP.NET Core.

Rendering HTML

The default Razor language is HTML. Rendering HTML from Razor markup is no different than rendering HTML from an HTML file. HTML markup in `.cshtml` Razor files is rendered by the server unchanged.

Razor syntax

Razor supports C# and uses the `@` symbol to transition from HTML to C#. Razor evaluates C# expressions and renders them in the HTML output.

When an `@` symbol is followed by a Razor reserved keyword, it transitions into Razor-specific markup. Otherwise, it transitions into plain HTML.

To escape an `@` symbol in Razor markup, use a second `@` symbol:

CSHTML

```
<p>@@Username</p>
```

The code is rendered in HTML with a single `@` symbol:

HTML

```
<p>@Username</p>
```

HTML attributes and content containing email addresses don't treat the `@` symbol as a transition character. The email addresses in the following example are untouched by Razor parsing:

CSHTML

```
<a href="mailto:Support@contoso.com">Support@contoso.com</a>
```

Scalable Vector Graphics (SVG)

SVG foreignObject elements are supported:

HTML

```
@{
    string message = "foreignObject example with Scalable Vector Graphics
(SVG)";
}

<svg width="200" height="200" xmlns="http://www.w3.org/2000/svg">
    <rect x="0" y="0" rx="10" ry="10" width="200" height="200"
stroke="black"
        fill="none" />
    <foreignObject x="20" y="20" width="160" height="160">
        <p>@message</p>
    </foreignObject>
</svg>
```

Implicit Razor expressions

Implicit Razor expressions start with `@` followed by C# code:

CSHTML

```
<p>@DateTime.Now</p>
<p>@DateTime.IsLeapYear(2016)</p>
```

With the exception of the C# `await` keyword, implicit expressions must not contain spaces. If the C# statement has a clear ending, spaces can be intermingled:

CSHTML

```
<p>@await DoSomething("hello", "world")</p>
```

Implicit expressions **cannot** contain C# generics, as the characters inside the brackets (`<>`) are interpreted as an HTML tag. The following code is **not** valid:

CSHTML

```
<p>@GenericMethod<int>()</p>
```

The preceding code generates a compiler error similar to one of the following:

- The "int" element wasn't closed. All elements must be either self-closing or have a matching end tag.
- Cannot convert method group 'GenericMethod' to non-delegate type 'object'. Did you intend to invoke the method?`

Generic method calls must be wrapped in an explicit Razor expression or a Razor code block.

Explicit Razor expressions

Explicit Razor expressions consist of an `@` symbol with balanced parenthesis. To render last week's time, the following Razor markup is used:

CSHTML

```
<p>Last week this time: @(DateTime.Now - TimeSpan.FromDays(7))</p>
```

Any content within the `@()` parenthesis is evaluated and rendered to the output.

Implicit expressions, described in the previous section, generally can't contain spaces. In the following code, one week isn't subtracted from the current time:

CSHTML

```
<p>Last week: @DateTime.Now - TimeSpan.FromDays(7)</p>
```

The code renders the following HTML:

HTML

```
<p>Last week: 7/7/2016 4:39:52 PM - TimeSpan.FromDays(7)</p>
```

Explicit expressions can be used to concatenate text with an expression result:

CSHTML

```
@{
    var joe = new Person("Joe", 33);
}

<p>Age@(joe.Age)</p>
```

Without the explicit expression, `<p>Age@joe.Age</p>` is treated as an email address, and `<p>Age@joe.Age</p>` is rendered. When written as an explicit expression, `<p>Age33</p>` is rendered.

Explicit expressions can be used to render output from generic methods in `.cshtml` files. The following markup shows how to correct the error shown earlier caused by the brackets of a C# generic. The code is written as an explicit expression:

CSHTML

```
<p>@(GenericMethod<int>())</p>
```

Expression encoding

C# expressions that evaluate to a string are HTML encoded. C# expressions that evaluate to `IHtmlContent` are rendered directly through `IHtmlContent.WriteTo`. C# expressions that don't evaluate to `IHtmlContent` are converted to a string by `ToString` and encoded before they're rendered.

CSHTML

```
@("<span>Hello World</span>")
```

The preceding code renders the following HTML:

HTML

```
&lt;span&gt;Hello World&lt;/span&gt;
```

The HTML is shown in the browser as plain text:

Hello World

`HtmlHelper.Raw` output isn't encoded but rendered as HTML markup.

> ⚠ **Warning**
>
> Using `HtmlHelper.Raw` on unsanitized user input is a security risk. User input might contain malicious JavaScript or other exploits. Sanitizing user input is difficult. Avoid using `HtmlHelper.Raw` with user input.

CSHTML

```
@Html.Raw("<span>Hello World</span>")
```

The code renders the following HTML:

HTML

```
<span>Hello World</span>
```

Razor code blocks

Razor code blocks start with `@` and are enclosed by `{}`. Unlike expressions, C# code inside code blocks isn't rendered. Code blocks and expressions in a view share the same scope and are defined in order:

CSHTML

```
@{
    var quote = "The future depends on what you do today. - Mahatma Gandhi";
}

<p>@quote</p>

@{
    quote = "Hate cannot drive out hate, only love can do that. - Martin
Luther King, Jr.";
}

<p>@quote</p>
```

The code renders the following HTML:

HTML

```
<p>The future depends on what you do today. - Mahatma Gandhi</p>
<p>Hate cannot drive out hate, only love can do that. - Martin Luther King,
Jr.</p>
```

In code blocks, declare local functions with markup to serve as templating methods:

CSHTML

```
@{
    void RenderName(string name)
    {
        <p>Name: <strong>@name</strong></p>
    }

    RenderName("Mahatma Gandhi");
    RenderName("Martin Luther King, Jr.");
}
```

The code renders the following HTML:

HTML

```
<p>Name: <strong>Mahatma Gandhi</strong></p>
<p>Name: <strong>Martin Luther King, Jr.</strong></p>
```

Implicit transitions

The default language in a code block is C#, but the Razor Page can transition back to HTML:

CSHTML

```
@{
    var inCSharp = true;
    <p>Now in HTML, was in C# @inCSharp</p>
}
```

Explicit delimited transition

To define a subsection of a code block that should render HTML, surround the characters for rendering with the Razor `<text>` tag:

CSHTML

```
@for (var i = 0; i < people.Length; i++)
{
    var person = people[i];
    <text>Name: @person.Name</text>
}
```

Use this approach to render HTML that isn't surrounded by an HTML tag. Without an HTML or Razor tag, a Razor runtime error occurs.

The `<text>` tag is useful to control whitespace when rendering content:

- Only the content between the `<text>` tag is rendered.
- No whitespace before or after the `<text>` tag appears in the HTML output.

Explicit line transition

To render the rest of an entire line as HTML inside a code block, use `@:` syntax:

CSHTML

```
@for (var i = 0; i < people.Length; i++)
{
    var person = people[i];
    @:Name: @person.Name
}
```

Without the `@:` in the code, a Razor runtime error is generated.

Extra `@` characters in a Razor file can cause compiler errors at statements later in the block. These extra `@` compiler errors:

- Can be difficult to understand because the actual error occurs before the reported error.
- Is common after combining multiple implicit and explicit expressions into a single code block.

Conditional attribute rendering

Razor automatically omits attributes that aren't needed. If the value passed in is `null` or `false`, the attribute isn't rendered.

For example, consider the following razor:

```
```

CSHTML

```
<div class="@false">False</div>
<div class="@null">Null</div>
<div class="@("")">Empty</div>
<div class="@("false")">False String</div>
<div class="@("active")">String</div>
<input type="checkbox" checked="@true" name="true" />
<input type="checkbox" checked="@false" name="false" />
<input type="checkbox" checked="@null" name="null" />
```

The preceding Razor markup generates the following HTML:

HTML

```
<div>False</div>
<div>Null</div>
<div class="">Empty</div>
<div class="false">False String</div>
<div class="active">String</div>
<input type="checkbox" checked="checked" name="true">
<input type="checkbox" name="false">
<input type="checkbox" name="null">
```

Control structures

Control structures are an extension of code blocks. All aspects of code blocks (transitioning to markup, inline C#) also apply to the following structures:

Conditionals `@if, else if, else, and @switch`

`@if` controls when code runs:

CSHTML

```
@if (value % 2 == 0)
{
    <p>The value was even.</p>
}
```

`else` and `else if` don't require the `@` symbol:

CSHTML

```
@if (value % 2 == 0)
{
```

```
    <p>The value was even.</p>
}
else if (value >= 1337)
{
    <p>The value is large.</p>
}
else
{
    <p>The value is odd and small.</p>
}
```

The following markup shows how to use a switch statement:

CSHTML

```
@switch (value)
{
    case 1:
        <p>The value is 1!</p>
        break;
    case 1337:
        <p>Your number is 1337!</p>
        break;
    default:
        <p>Your number wasn't 1 or 1337.</p>
        break;
}
```

Looping `@for, @foreach, @while, and @do while`

Templated HTML can be rendered with looping control statements. To render a list of people:

CSHTML

```
@{
    var people = new Person[]
    {
          new Person("Weston", 33),
          new Person("Johnathon", 41),
          ...
    };
}
```

The following looping statements are supported:

`@for`

```
```

CSHTML

```
@for (var i = 0; i < people.Length; i++)
{
    var person = people[i];
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>
}
```

`@foreach`

CSHTML

```
@foreach (var person in people)
{
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>
}
```

`@while`

CSHTML

```
@{ var i = 0; }
@while (i < people.Length)
{
    var person = people[i];
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>

    i++;
}
```

`@do while`

CSHTML

```
@{ var i = 0; }
@do
{
    var person = people[i];
    <p>Name: @person.Name</p>
    <p>Age: @person.Age</p>

    i++;
} while (i < people.Length);
```

Compound `@using`

In C#, a `using` statement is used to ensure an object is disposed. In Razor, the same mechanism is used to create HTML Helpers that contain additional content. In the following code, HTML Helpers render a `<form>` tag with the `@using` statement:

CSHTML

```
@using (Html.BeginForm())
{
    <div>
        <label>Email: <input type="email" id="Email" value=""></label>
        <button>Register</button>
    </div>
}
```

`@try, catch, finally`

Exception handling is similar to C#:

CSHTML

```
@try
{
    throw new InvalidOperationException("You did something invalid.");
}
catch (Exception ex)
{
    <p>The exception message: @ex.Message</p>
}
finally
{
    <p>The finally statement.</p>
}
```

`@lock`

Razor has the capability to protect critical sections with lock statements:

CSHTML

```
@lock (SomeLock)
{
    // Do critical section work
}
```

Comments

Razor supports C# and HTML comments:

```cshtml
@{
    /* C# comment */
    // Another C# comment
}
<!-- HTML comment -->
```

The code renders the following HTML:

```html
<!-- HTML comment -->
```

Razor comments are removed by the server before the webpage is rendered. Razor uses `@* *@` to delimit comments. The following code is commented out, so the server doesn't render any markup:

```cshtml
@*
    @{
        /* C# comment */
        // Another C# comment
    }
    <!-- HTML comment -->
*@
```

Directives

Razor directives are represented by implicit expressions with reserved keywords following the `@` symbol. A directive typically changes the way a view is compiled or functions.

Understanding how Razor generates code for a view makes it easier to understand how directives work.

```cshtml
@{
    var quote = "Getting old ain't for wimps! - Anonymous";
```

```
}

<div>Quote of the Day: @quote</div>
```

The code generates a class similar to the following:

C#

```
public class _Views_Something_cshtml : RazorPage<dynamic>
{
    public override async Task ExecuteAsync()
    {
        var output = "Getting old ain't for wimps! - Anonymous";

        WriteLiteral("/r/n<div>Quote of the Day: ");
        Write(output);
        WriteLiteral("</div>");
    }
}
```

Later in this article, the section Inspect the Razor C# class generated for a view explains how to view this generated class.

`@attribute`

The `@attribute` directive adds the given attribute to the class of the generated page or view. The following example adds the `[Authorize]` attribute:

CSHTML

```
@attribute [Authorize]
```

The `@attribute` directive can also be used to supply a constant-based route template in a Razor component. In the following example, the `@page` directive in a component is replaced with the `@attribute` directive and the constant-based route template in `Constants.CounterRoute`, which is set elsewhere in the app to "`/counter`":

diff

```
- @page "/counter"
+ @attribute [Route(Constants.CounterRoute)]
```

`@code`

This scenario only applies to Razor components (`.razor`).

The `@code` block enables a Razor component to add C# members (fields, properties, and methods) to a component:

razor

```
@code {
    // C# members (fields, properties, and methods)
}
```

For Razor components, `@code` is an alias of @functions and recommended over `@functions`. More than one `@code` block is permissible.

`@functions`

The `@functions` directive enables adding C# members (fields, properties, and methods) to the generated class:

CSHTML

```
@functions {
    // C# members (fields, properties, and methods)
}
```

In Razor components, use `@code` over `@functions` to add C# members.

For example:

CSHTML

```
@functions {
    public string GetHello()
    {
        return "Hello";
    }
}

<div>From method: @GetHello()</div>
```

The code generates the following HTML markup:

HTML

```
<div>From method: Hello</div>
```

The following code is the generated Razor C# class:

C#

```
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc.Razor;

public class _Views_Home_Test_cshtml : RazorPage<dynamic>
{
    // Functions placed between here
    public string GetHello()
    {
        return "Hello";
    }
    // And here.
#pragma warning disable 1998
    public override async Task ExecuteAsync()
    {
        WriteLiteral("\r\n<div>From method: ");
        Write(GetHello());
        WriteLiteral("</div>\r\n");
    }
#pragma warning restore 1998
```

`@functions` methods serve as templating methods when they have markup:

CSHTML

```
@{
    RenderName("Mahatma Gandhi");
    RenderName("Martin Luther King, Jr.");
}

@functions {
    private void RenderName(string name)
    {
        <p>Name: <strong>@name</strong></p>
    }
}
```

The code renders the following HTML:

HTML

```
<p>Name: <strong>Mahatma Gandhi</strong></p>
<p>Name: <strong>Martin Luther King, Jr.</strong></p>
```

`@implements`

The `@implements` directive implements an interface for the generated class.

The following example implements System.IDisposable so that the Dispose method can be called:

CSHTML

```
@implements IDisposable

<h1>Example</h1>

@functions {
    private bool _isDisposed;

    ...

    public void Dispose() => _isDisposed = true;
}
```

`@inherits`

The `@inherits` directive provides full control of the class the view inherits:

CSHTML

```
@inherits TypeNameOfClassToInheritFrom
```

The following code is a custom Razor page type:

C#

```
using Microsoft.AspNetCore.Mvc.Razor;

public abstract class CustomRazorPage<TModel> : RazorPage<TModel>
{
    public string CustomText { get; } =
        "Gardyloo! - A Scottish warning yelled from a window before dumping"
+
        "a slop bucket on the street below.";
}
```

The `CustomText` is displayed in a view:

CSHTML

```
@inherits CustomRazorPage<TModel>
```

```
<div>Custom text: @CustomText</div>
```

The code renders the following HTML:

HTML

```
<div>
    Custom text: Gardyloo! - A Scottish warning yelled from a window before
dumping
    a slop bucket on the street below.
</div>
```

`@model` and `@inherits` can be used in the same view. `@inherits` can be in a `_ViewImports.cshtml` file that the view imports:

CSHTML

```
@inherits CustomRazorPage<TModel>
```

The following code is an example of a strongly-typed view:

CSHTML

```
@inherits CustomRazorPage<TModel>

<div>The Login Email: @Model.Email</div>
<div>Custom text: @CustomText</div>
```

If "rick@contoso.com" is passed in the model, the view generates the following HTML markup:

HTML

```
<div>The Login Email: rick@contoso.com</div>
<div>
    Custom text: Gardyloo! - A Scottish warning yelled from a window before
dumping
    a slop bucket on the street below.
</div>
```

`@inject`

The `@inject` directive enables the Razor Page to inject a service from the service container into a view. For more information, see Dependency injection into views.

`@layout`

This scenario only applies to Razor components (`.razor`).

The `@layout` directive specifies a layout for routable Razor components that have an `@page` directive. Layout components are used to avoid code duplication and inconsistency. For more information, see ASP.NET Core Blazor layouts.

`@model`

This scenario only applies to MVC views and Razor Pages (`.cshtml`).

The `@model` directive specifies the type of the model passed to a view or page:

```
CSHTML

@model TypeNameOfModel
```

In an ASP.NET Core MVC or Razor Pages app created with individual user accounts, `Views/Account/Login.cshtml` contains the following model declaration:

```
CSHTML

@model LoginViewModel
```

The class generated inherits from `RazorPage<LoginViewModel>`:

```
C#

public class _Views_Account_Login_cshtml : RazorPage<LoginViewModel>
```

Razor exposes a `Model` property for accessing the model passed to the view:

```
CSHTML

<div>The Login Email: @Model.Email</div>
```

The `@model` directive specifies the type of the `Model` property. The directive specifies the `T` in `RazorPage<T>` that the generated class that the view derives from. If the `@model` directive isn't specified, the `Model` property is of type `dynamic`. For more information, see Strongly typed models and the @model keyword.

`@namespace`

The `@namespace` directive:

- Sets the namespace of the class of the generated Razor page, MVC view, or Razor component.
- Sets the root derived namespaces of a pages, views, or components classes from the closest imports file in the directory tree, `_ViewImports.cshtml` (views or pages) or `_Imports.razor` (Razor components).

CSHTML

```
@namespace Your.Namespace.Here
```

For the Razor Pages example shown in the following table:

- Each page imports `Pages/_ViewImports.cshtml`.
- `Pages/_ViewImports.cshtml` contains `@namespace Hello.World`.
- Each page has `Hello.World` as the root of it's namespace.

Expand table

Page	Namespace
`Pages/Index.cshtml`	`Hello.World`
`Pages/MorePages/Page.cshtml`	`Hello.World.MorePages`
`Pages/MorePages/EvenMorePages/Page.cshtml`	`Hello.World.MorePages.EvenMorePages`

The preceding relationships apply to import files used with MVC views and Razor components.

When multiple import files have a `@namespace` directive, the file closest to the page, view, or component in the directory tree is used to set the root namespace.

If the `EvenMorePages` folder in the preceding example has an imports file with `@namespace Another.Planet` (or the `Pages/MorePages/EvenMorePages/Page.cshtml` file contains `@namespace Another.Planet`), the result is shown in the following table.

Expand table

Page	Namespace
`Pages/Index.cshtml`	`Hello.World`
`Pages/MorePages/Page.cshtml`	`Hello.World.MorePages`
`Pages/MorePages/EvenMorePages/Page.cshtml`	`Another.Planet`

`@page`

The `@page` directive has different effects depending on the type of the file where it appears. The directive:

- In a `.cshtml` file indicates that the file is a Razor Page. For more information, see Custom routes and Introduction to Razor Pages in ASP.NET Core.
- Specifies that a Razor component should handle requests directly. For more information, see ASP.NET Core Blazor routing and navigation.

`@preservewhitespace`

This scenario only applies to Razor components (`.razor`).

When set to `false` (default), whitespace in the rendered markup from Razor components (`.razor`) is removed if:

- Leading or trailing within an element.
- Leading or trailing within a `RenderFragment` parameter. For example, child content passed to another component.
- It precedes or follows a C# code block, such as `@if` or `@foreach`.

`@rendermode`

This scenario only applies to Razor components (`.razor`).

Sets the render mode of a Razor component:

- `InteractiveServer`: Applies interactive server rendering using Blazor Server.
- `InteractiveWebAssembly`: Applies interactive WebAssembly rendering using Blazor WebAssembly.
- `InteractiveAuto`: Initially applies interactive WebAssembly rendering using Blazor Server, and then applies interactive WebAssembly rendering using WebAssembly on subsequent visits after the Blazor bundle is downloaded.

For a component instance:

```razor
<... @rendermode="InteractiveServer" />
```

In the component definition:

```razor
@rendermode InteractiveServer
```

> **Note**
>
> Blazor templates include a static `using` directive for RenderMode in the app's `_Imports` file (`Components/_Imports.razor`) for shorter `@rendermode` syntax:
>
> ```razor
> @using static Microsoft.AspNetCore.Components.Web.RenderMode
> ```
>
> Without the preceding directive, components must specify the static RenderMode class in `@rendermode` syntax explicitly:
>
> ```razor
> <Dialog @rendermode="RenderMode.InteractiveServer" />
> ```

For more information, including guidance on disabling prerendering with the directive/directive attribute, see ASP.NET Core Blazor render modes.

`@section`

This scenario only applies to MVC views and Razor Pages (`.cshtml`).

The `@section` directive is used in conjunction with MVC and Razor Pages layouts to enable views or pages to render content in different parts of the HTML page. For more information, see Layout in ASP.NET Core.

`@typeparam`

This scenario only applies to Razor components (`.razor`).

The `@typeparam` directive declares a generic type parameter for the generated component class:

```razor
@typeparam TEntity
```

Generic types with where type constraints are supported:

```razor
@typeparam TEntity where TEntity : IEntity
```

For more information, see the following articles:

- ASP.NET Core Razor component generic type support
- ASP.NET Core Blazor templated components

`@using`

The `@using` directive adds the C# `using` directive to the generated view:

```CSHTML
@using System.IO
@{
    var dir = Directory.GetCurrentDirectory();
}
<p>@dir</p>
```

In Razor components, `@using` also controls which components are in scope.

Directive attributes

Razor directive attributes are represented by implicit expressions with reserved keywords following the `@` symbol. A directive attribute typically changes the way an element is compiled or functions.

`@attributes`

This scenario only applies to Razor components (`.razor`).

`@attributes` allows a component to render non-declared attributes. For more information, see ASP.NET Core Blazor attribute splatting and arbitrary parameters.

`@bind`

This scenario only applies to Razor components (`.razor`).

Data binding in components is accomplished with the `@bind` attribute. For more information, see ASP.NET Core Blazor data binding.

`@bind:culture`

This scenario only applies to Razor components (`.razor`).

Use the `@bind:culture` attribute with the @bind attribute to provide a System.Globalization.CultureInfo for parsing and formatting a value. For more information, see ASP.NET Core Blazor globalization and localization.

`@formname`

This scenario only applies to Razor components (`.razor`).

`@formname` assigns a form name to a Razor component's plain HTML form or a form based on EditForm (Editform documentation). The value of `@formname` should be unique, which prevents form collisions in the following situations:

- A form is placed in a component with multiple forms.
- A form is sourced from an external class library, commonly a NuGet package, for a component with multiple forms, and the app author doesn't control the source code of the library to set a different external form name than a name used by another form in the component.

For more information and examples, see ASP.NET Core Blazor forms overview.

`@on{EVENT}`

This scenario only applies to Razor components (`.razor`).

Razor provides event handling features for components. For more information, see ASP.NET Core Blazor event handling.

`@on{EVENT}:preventDefault`

This scenario only applies to Razor components (`.razor`).

Prevents the default action for the event.

`@on{EVENT}:stopPropagation`

This scenario only applies to Razor components (`.razor`).

Stops event propagation for the event.

`@key`

This scenario only applies to Razor components (`.razor`).

The `@key` directive attribute causes the components diffing algorithm to guarantee preservation of elements or components based on the key's value. For more information, see Retain element, component, and model relationships in ASP.NET Core Blazor.

`@ref`

This scenario only applies to Razor components (`.razor`).

Component references (`@ref`) provide a way to reference a component instance so that you can issue commands to that instance. For more information, see ASP.NET Core Razor components.

Templated Razor delegates

This scenario only applies to MVC views and Razor Pages (`.cshtml`).

Razor templates allow you to define a UI snippet with the following format:

```
CSHTML

@<tag>...</tag>
```

The following example illustrates how to specify a templated Razor delegate as a Func<T,TResult>. The dynamic type is specified for the parameter of the method that

the delegate encapsulates. An object type is specified as the return value of the delegate. The template is used with a List<T> of `Pet` that has a `Name` property.

C#

```
public class Pet
{
    public string Name { get; set; }
}
```

CSHTML

```
@{
    Func<dynamic, object> petTemplate = @<p>You have a pet named
<strong>@item.Name</strong>.</p>;

    var pets = new List<Pet>
    {
        new Pet { Name = "Rin Tin Tin" },
        new Pet { Name = "Mr. Bigglesworth" },
        new Pet { Name = "K-9" }
    };
}
```

The template is rendered with `pets` supplied by a `foreach` statement:

CSHTML

```
@foreach (var pet in pets)
{
    @petTemplate(pet)
}
```

Rendered output:

HTML

```
<p>You have a pet named <strong>Rin Tin Tin</strong>.</p>
<p>You have a pet named <strong>Mr. Bigglesworth</strong>.</p>
<p>You have a pet named <strong>K-9</strong>.</p>
```

You can also supply an inline Razor template as an argument to a method. In the following example, the `Repeat` method receives a Razor template. The method uses the template to produce HTML content with repeats of items supplied from a list:

CSHTML

```
@using Microsoft.AspNetCore.Html

@functions {
    public static IHtmlContent Repeat(IEnumerable<dynamic> items, int times,
        Func<dynamic, IHtmlContent> template)
    {
        var html = new HtmlContentBuilder();

        foreach (var item in items)
        {
            for (var i = 0; i < times; i++)
            {
                html.AppendHtml(template(item));
            }
        }

        return html;
    }
}
```

Using the list of pets from the prior example, the `Repeat` method is called with:

- List<T> of `Pet`.
- Number of times to repeat each pet.
- Inline template to use for the list items of an unordered list.

CSHTML

```
<ul>
    @Repeat(pets, 3, @<li>@item.Name</li>)
</ul>
```

Rendered output:

HTML

```
<ul>
    <li>Rin Tin Tin</li>
    <li>Rin Tin Tin</li>
    <li>Rin Tin Tin</li>
    <li>Mr. Bigglesworth</li>
    <li>Mr. Bigglesworth</li>
    <li>Mr. Bigglesworth</li>
    <li>K-9</li>
    <li>K-9</li>
    <li>K-9</li>
</ul>
```

Tag Helpers

This scenario only applies to MVC views and Razor Pages (`.cshtml`).

There are three directives that pertain to Tag Helpers.

Expand table

Directive	Function
@addTagHelper	Makes Tag Helpers available to a view.
@removeTagHelper	Removes Tag Helpers previously added from a view.
@tagHelperPrefix	Specifies a tag prefix to enable Tag Helper support and to make Tag Helper usage explicit.

Razor reserved keywords

Razor keywords

- `page`
- `namespace`
- `functions`
- `inherits`
- `model`
- `section`
- `helper` (Not currently supported by ASP.NET Core)

Razor keywords are escaped with `@(Razor Keyword)` (for example, `@(functions)`).

C# Razor keywords

- `case`
- `do`
- `default`
- `for`
- `foreach`
- `if`
- `else`
- `lock`

- `switch`
- `try`
- `catch`
- `finally`
- `using`
- `while`

C# Razor keywords must be double-escaped with `@(@C# Razor Keyword)` (for example, `@(@case)`). The first `@` escapes the Razor parser. The second `@` escapes the C# parser.

Reserved keywords not used by Razor

- `class`

Inspect the Razor C# class generated for a view

The Razor SDK handles compilation of Razor files. By default, the generated code files aren't emitted. To enable emitting the code files, set the `EmitCompilerGeneratedFiles` directive in the project file (`.csproj`) to `true`:

XML

```
<PropertyGroup>
  <EmitCompilerGeneratedFiles>true</EmitCompilerGeneratedFiles>
</PropertyGroup>
```

When building a 6.0 project (`net6.0`) in the `Debug` build configuration, the Razor SDK generates an `obj/Debug/net6.0/generated/` directory in the project root. Its subdirectory contains the emitted Razor page code files.

View lookups and case sensitivity

The Razor view engine performs case-sensitive lookups for views. However, the actual lookup is determined by the underlying file system:

- File based source:
  - On operating systems with case insensitive file systems (for example, Windows), physical file provider lookups are case insensitive. For example, `return View("Test")` results in matches for `/Views/Home/Test.cshtml`, `/Views/home/test.cshtml`, and any other casing variant.

    - On case-sensitive file systems (for example, Linux, OSX, and with `EmbeddedFileProvider`), lookups are case-sensitive. For example, `return View("Test")` specifically matches `/Views/Home/Test.cshtml`.
- Precompiled views: With ASP.NET Core 2.0 and later, looking up precompiled views is case insensitive on all operating systems. The behavior is identical to physical file provider's behavior on Windows. If two precompiled views differ only in case, the result of lookup is non-deterministic.

Developers are encouraged to match the casing of file and directory names to the casing of:

- Area, controller, and action names.
- Razor Pages.

Matching case ensures the deployments find their views regardless of the underlying file system.

Imports used by Razor

The following imports are generated by the ASP.NET Core web templates to support Razor Files:

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Rendering;
using Microsoft.AspNetCore.Mvc.ViewFeatures;
```

Create reusable UI using the Razor class library project in ASP.NET Core

Article • 07/23/2024

By Rick Anderson

Razor views, pages, controllers, page models, Razor components, View components, and data models can be built into a Razor class library (RCL). The RCL can be packaged and reused. Applications can include the RCL and override the views and pages it contains. When a view, partial view, or Razor Page is found in both the web app and the RCL, the Razor markup (`.cshtml` file) in the web app takes precedence.

For information on how to integrate npm and webpack into the build process for a RCL, see Build client web assets for your Razor Class Library.

Create a class library containing Razor UI

Visual Studio

- From Visual Studio select **Create new a new project**.
- Select **Razor Class Library** > **Next**.
- Name the library (for example, "RazorClassLib"), > **Create**. To avoid a file name collision with the generated view library, ensure the library name doesn't end in `.Views`.
- Select **Support pages and views** if you need the library to contain pages and/or views. By default, only Razor components are supported. Select **Create**.

The Razor Class Library template defaults to Razor component development by default. The **Support pages and views** option supports pages and views. For more information on RCL support in Blazor, see Consume ASP.NET Core Razor components from a Razor class library (RCL).

Add Razor files to the RCL.

The ASP.NET Core templates assume the RCL content is in the `Areas` folder. See RCL Pages layout below to create an RCL that exposes content in `~/Pages` rather than `~/Areas/Pages`.

Reference RCL content

The RCL can be referenced by:

- NuGet package. See Creating NuGet packages and dotnet add package and Create and publish a NuGet package.
- `{ProjectName}.csproj`. See dotnet-add reference.

Override views, partial views, and pages

When a view, partial view, or Razor Page is found in both the web app and the RCL, the Razor markup (`.cshtml` file) in the web app takes precedence. For example, add `WebApp1/Areas/MyFeature/Pages/Page1.cshtml` to WebApp1, and Page1 in the WebApp1 will take precedence over Page1 in the RCL.

In the sample download, rename `WebApp1/Areas/MyFeature2` to `WebApp1/Areas/MyFeature` to test precedence.

Copy the `RazorUIClassLib/Areas/MyFeature/Pages/Shared/_Message.cshtml` partial view to `WebApp1/Areas/MyFeature/Pages/Shared/_Message.cshtml`. Update the markup to indicate the new location. Build and run the app to verify the app's version of the partial is being used.

If the RCL uses Razor Pages, enable the Razor Pages services and endpoints in the hosting app:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();
```

```
app.UseAuthorization();

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.MapRazorPages();
app.Run();
```

RCL Pages layout

To reference RCL content as though it is part of the web app's `Pages` folder, create the RCL project with the following file structure:

- `RazorUIClassLib/Pages`
- `RazorUIClassLib/Pages/Shared`

Suppose `RazorUIClassLib/Pages/Shared` contains two partial files: `_Header.cshtml` and `_Footer.cshtml`. The `<partial>` tags could be added to `_Layout.cshtml` file:

CSHTML

```
<body>
  <partial name="_Header">
  @RenderBody()
  <partial name="_Footer">
</body>
```

Add the `_ViewStart.cshtml` file to the RCL project's `Pages` folder to use the `_Layout.cshtml` file from the host web app:

CSHTML

```
@{
    Layout = "_Layout";
}
```

Create an RCL with static assets

An RCL may require companion static assets that can be referenced by either the RCL or the consuming app of the RCL. ASP.NET Core allows creating RCLs that include static assets that are available to a consuming app.

To include companion assets as part of an RCL, create a `wwwroot` folder in the class library and include any required files in that folder.

When packing an RCL, all companion assets in the `wwwroot` folder are automatically included in the package.

Use the `dotnet pack` command rather than the NuGet.exe version `nuget pack`.

Add client web assets to the build process

Integrating client web assets into the build pipeline is nontrivial. See Build client web assets for your Razor Class Library for more information.

Exclude static assets

To exclude static assets, add the desired exclusion path to the `$(DefaultItemExcludes)` property group in the project file. Separate entries with a semicolon (`;`).

In the following example, the `lib.css` stylesheet in the `wwwroot` folder isn't considered a static asset and isn't included in the published RCL:

XML

```
<PropertyGroup>

<DefaultItemExcludes>$(DefaultItemExcludes);wwwroot\lib.css</DefaultItemExcl
udes>
</PropertyGroup>
```

Typescript integration

To include TypeScript files in an RCL:

1. Reference the Microsoft.TypeScript.MSBuild NuGet package in the project.

> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.

2. Place the TypeScript files (`.ts`) outside of the `wwwroot` folder. For example, place the files in a `Client` folder.

3. Configure the TypeScript build output for the `wwwroot` folder. Set the `TypescriptOutDir` property inside of a `PropertyGroup` in the project file:

   XML

   ```
   <TypescriptOutDir>wwwroot</TypescriptOutDir>
   ```

4. Include the TypeScript target as a dependency of the `PrepareForBuildDependsOn` target by adding the following target inside of a `PropertyGroup` in the project file:

   XML

   ```
   <PrepareForBuildDependsOn>
     CompileTypeScript;
     GetTypeScriptOutputForPublishing;$(PrepareForBuildDependsOn)
   </PrepareForBuildDependsOn>
   ```

Consume content from a referenced RCL

The files included in the `wwwroot` folder of the RCL are exposed to either the RCL or the consuming app under the prefix `_content/{PACKAGE ID}/`. For example, a library with an assembly name of `Razor.Class.Lib` and without a `<PackageId>` specified in its project file results in a path to static content at `_content/Razor.Class.Lib/`. When producing a NuGet package and the assembly name isn't the same as the package ID (<PackageId> in the library's project file), use the package ID as specified in the project file for `{PACKAGE ID}`.

The consuming app references static assets provided by the library with `<script>`, `<style>`, `<img>`, and other HTML tags. The consuming app must have static file support enabled in:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();
builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
```

```
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.MapRazorPages();
app.Run();
```

When running the consuming app from build output (`dotnet run`), static web assets are enabled by default in the Development environment. To support assets in other environments when running from build output, call UseStaticWebAssets on the host builder in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.WebHost.UseWebRoot("wwwroot");
builder.WebHost.UseStaticWebAssets();

builder.Services.AddRazorPages();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapRazorPages();

app.Run();
```

Calling `UseStaticWebAssets` isn't required when running an app from published output (`dotnet publish`).

Multi-project development flow

When the consuming app runs:

- The assets in the RCL stay in their original folders. The assets aren't moved to the consuming app.
- Any change within the RCL's `wwwroot` folder is reflected in the consuming app after the RCL is rebuilt and without rebuilding the consuming app.

When the RCL is built, a manifest is produced that describes the static web asset locations. The consuming app reads the manifest at runtime to consume the assets from referenced projects and packages. When a new asset is added to an RCL, the RCL must be rebuilt to update its manifest before a consuming app can access the new asset.

Publish

When the app is published, the companion assets from all referenced projects and packages are copied into the `wwwroot` folder of the published app under `_content/{PACKAGE ID}/`. When producing a NuGet package and the assembly name isn't the same as the package ID (<PackageId> in the library's project file), use the package ID as specified in the project file for `{PACKAGE ID}` when examining the `wwwroot` folder for the published assets.

ASP.NET Core built-in Tag Helpers

Article • 06/03/2022

By Peter Kellner

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

There are built-in Tag Helpers which aren't listed in this document. The unlisted Tag Helpers are used internally by the Razor view engine. The Tag Helper for the `~` (tilde) character is unlisted. The tilde Tag Helper expands to the root path of the website.

Tag Helpers in ASP.NET Core

Article • 03/05/2024

By Rick Anderson

What are Tag Helpers

Tag Helpers enable server-side code to participate in creating and rendering HTML elements in Razor files. For example, the built-in `ImageTagHelper` can append a version number to the image name. Whenever the image changes, the server generates a new unique version for the image, so clients are guaranteed to get the current image (instead of a stale cached image). There are many built-in Tag Helpers for common tasks - such as creating forms, links, loading assets and more - and even more available in public GitHub repositories and as NuGet packages. Tag Helpers are authored in C#, and they target HTML elements based on element name, attribute name, or parent tag. For example, the built-in `LabelTagHelper` can target the HTML `<label>` element when the `LabelTagHelper` attributes are applied. If you're familiar with HTML Helpers, Tag Helpers reduce the explicit transitions between HTML and C# in Razor views. In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. Tag Helpers compared to HTML Helpers explains the differences in more detail.

Tag Helpers aren't supported in Razor components. For more information, see ASP.NET Core Razor components.

What Tag Helpers provide

An HTML-friendly development experience

For the most part, Razor markup using Tag Helpers looks like standard HTML. Front-end designers conversant with HTML/CSS/JavaScript can edit Razor without learning C# Razor syntax.

A rich IntelliSense environment for creating HTML and Razor markup

This is in sharp contrast to HTML Helpers, the previous approach to server-side creation of markup in Razor views. Tag Helpers compared to HTML Helpers explains the differences in more detail. IntelliSense support for Tag Helpers explains the IntelliSense

environment. Even developers experienced with Razor C# syntax are more productive using Tag Helpers than writing C# Razor markup.

A way to make you more productive and able to produce more robust, reliable, and maintainable code using information only available on the server

For example, historically the mantra on updating images was to change the name of the image when you change the image. Images should be aggressively cached for performance reasons, and unless you change the name of an image, you risk clients getting a stale copy. Historically, after an image was edited, the name had to be changed and each reference to the image in the web app needed to be updated. Not only is this very labor intensive, it's also error prone (you could miss a reference, accidentally enter the wrong string, etc.) The built-in `ImageTagHelper` can do this for you automatically. The `ImageTagHelper` can append a version number to the image name, so whenever the image changes, the server automatically generates a new unique version for the image. Clients are guaranteed to get the current image. This robustness and labor savings comes essentially free by using the `ImageTagHelper`.

Most built-in Tag Helpers target standard HTML elements and provide server-side attributes for the element. For example, the `<input>` element used in many views in the *Views/Account* folder contains the `asp-for` attribute. This attribute extracts the name of the specified model property into the rendered HTML. Consider a Razor view with the following model:

C#

```
public class Movie
{
    public int ID { get; set; }
    public string Title { get; set; }
    public DateTime ReleaseDate { get; set; }
    public string Genre { get; set; }
    public decimal Price { get; set; }
}
```

The following Razor markup:

CSHTML

```
<label asp-for="Movie.Title"></label>
```

Generates the following HTML:

HTML

```
<label for="Movie_Title">Title</label>
```

The `asp-for` attribute is made available by the `For` property in the LabelTagHelper. See Author Tag Helpers for more information.

Managing Tag Helper scope

Tag Helpers scope is controlled by a combination of `@addTagHelper`, `@removeTagHelper`, and the "!" opt-out character.

`@addTagHelper` makes Tag Helpers available

If you create a new ASP.NET Core web app named *AuthoringTagHelpers*, the following `Views/_ViewImports.cshtml` file will be added to your project:

CSHTML

```
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper *, AuthoringTagHelpers
```

The `@addTagHelper` directive makes Tag Helpers available to the view. In this case, the view file is `Pages/_ViewImports.cshtml`, which by default is inherited by all files in the *Pages* folder and subfolders; making Tag Helpers available. The code above uses the wildcard syntax ("*") to specify that all Tag Helpers in the specified assembly (*Microsoft.AspNetCore.Mvc.TagHelpers*) will be available to every view file in the *Views* directory or subdirectory. The first parameter after `@addTagHelper` specifies the Tag Helpers to load (we are using "*" for all Tag Helpers), and the second parameter "Microsoft.AspNetCore.Mvc.TagHelpers" specifies the assembly containing the Tag Helpers. *Microsoft.AspNetCore.Mvc.TagHelpers* is the assembly for the built-in ASP.NET Core Tag Helpers.

To expose all of the Tag Helpers in this project (which creates an assembly named *AuthoringTagHelpers*), you would use the following:

CSHTML

```
@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper *, AuthoringTagHelpers
```

If your project contains an `EmailTagHelper` with the default namespace (`AuthoringTagHelpers.TagHelpers.EmailTagHelper`), you can provide the fully qualified name (FQN) of the Tag Helper:

CSHTML

```
@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper AuthoringTagHelpers.TagHelpers.EmailTagHelper,
AuthoringTagHelpers
```

To add a Tag Helper to a view using an FQN, you first add the FQN (`AuthoringTagHelpers.TagHelpers.EmailTagHelper`), and then the assembly name (*AuthoringTagHelpers*). Most developers prefer to use the "*" wildcard syntax. The wildcard syntax allows you to insert the wildcard character "*" as the suffix in an FQN. For example, any of the following directives will bring in the `EmailTagHelper`:

CSHTML

```
@addTagHelper AuthoringTagHelpers.TagHelpers.E*, AuthoringTagHelpers
@addTagHelper AuthoringTagHelpers.TagHelpers.Email*, AuthoringTagHelpers
```

As mentioned previously, adding the `@addTagHelper` directive to the `Views/_ViewImports.cshtml` file makes the Tag Helper available to all view files in the *Views* directory and subdirectories. You can use the `@addTagHelper` directive in specific view files if you want to opt-in to exposing the Tag Helper to only those views.

`@removeTagHelper` removes Tag Helpers

The `@removeTagHelper` has the same two parameters as `@addTagHelper`, and it removes a Tag Helper that was previously added. For example, `@removeTagHelper` applied to a specific view removes the specified Tag Helper from the view. Using `@removeTagHelper` in a `Views/Folder/_ViewImports.cshtml` file removes the specified Tag Helper from all of the views in *Folder*.

Controlling Tag Helper scope with the `_ViewImports.cshtml` file

You can add a `_ViewImports.cshtml` to any view folder, and the view engine applies the directives from both that file and the `Views/_ViewImports.cshtml` file. If you added an empty `Views/Home/_ViewImports.cshtml` file for the *Home* views, there would be no

change because the `_ViewImports.cshtml` file is additive. Any `@addTagHelper` directives you add to the `Views/Home/_ViewImports.cshtml` file (that are not in the default `Views/_ViewImports.cshtml` file) would expose those Tag Helpers to views only in the *Home* folder.

Opting out of individual elements

You can disable a Tag Helper at the element level with the Tag Helper opt-out character ("!"). For example, `Email` validation is disabled in the `<span>` with the Tag Helper opt-out character:

CSHTML

```
<!span asp-validation-for="Email" class="text-danger"></!span>
```

You must apply the Tag Helper opt-out character to the opening and closing tag. (The Visual Studio editor automatically adds the opt-out character to the closing tag when you add one to the opening tag). After you add the opt-out character, the element and Tag Helper attributes are no longer displayed in a distinctive font.

Using `@tagHelperPrefix` to make Tag Helper usage explicit

The `@tagHelperPrefix` directive allows you to specify a tag prefix string to enable Tag Helper support and to make Tag Helper usage explicit. For example, you could add the following markup to the `Views/_ViewImports.cshtml` file:

CSHTML

```
@tagHelperPrefix th:
```

In the code image below, the Tag Helper prefix is set to `th:`, so only those elements using the prefix `th:` support Tag Helpers (Tag Helper-enabled elements have a distinctive font). The `<label>` and `<input>` elements have the Tag Helper prefix and are Tag Helper-enabled, while the `<span>` element doesn't.

```
<div class="form-group">
    <th:label asp-for="Password" class="col-md-2"></th:label>
    <div class="col-md-10">
        <th:input asp-for="Password" class="form-control" />
        <span asp-validation-for="Password" class="text-danger"></span>
    </div>
</div>
```

The same hierarchy rules that apply to `@addTagHelper` also apply to `@tagHelperPrefix`.

Self-closing Tag Helpers

Many Tag Helpers can't be used as self-closing tags. Some Tag Helpers are designed to be self-closing tags. Using a Tag Helper that was not designed to be self-closing suppresses the rendered output. Self-closing a Tag Helper results in a self-closing tag in the rendered output. For more information, see this note in Authoring Tag Helpers.

C# in Tag Helpers attribute/declaration

Tag Helpers do not allow C# in the element's attribute or tag declaration area. For example, the following code is not valid:

CSHTML

```
<input asp-for="LastName"
       @(Model?.LicenseId == null ? "disabled" : string.Empty) />
```

The preceding code can be written as:

CSHTML

```
<input asp-for="LastName"
       disabled="@(Model?.LicenseId == null)" />
```

Normally, the `@` operator inserts a textual representation of an expression into the rendered HTML markup. However, when an expression evaluates to logical `false`, the framework removes the attribute instead. In the preceding example, the `disabled` attribute is set to `true` if either `Model` or `LicenseId` is `null`.

Tag helper initializers

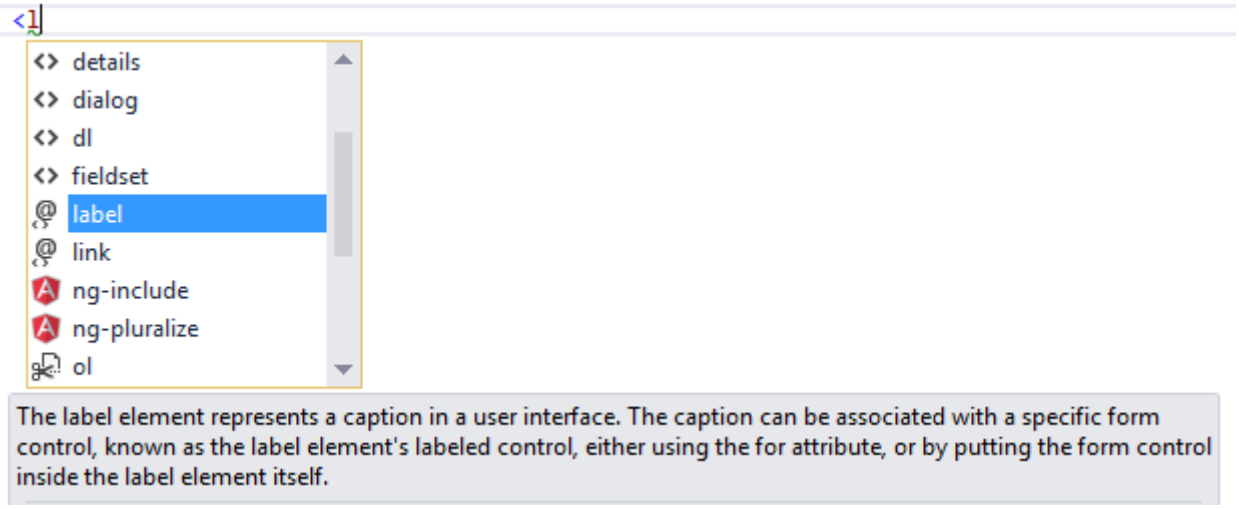
While attributes can be used to configure individual instances of tag helpers, ITagHelperInitializer<TTagHelper> can be used to configure all tag helper instances of a specific kind. Consider the following example of a tag helper initializer that configures the `asp-append-version` attribute or `AppendVersion` property for all instances of `ScriptTagHelper` in the app:

C#

```
public class AppendVersionTagHelperInitializer :
ITagHelperInitializer<ScriptTagHelper>
{
    public void Initialize(ScriptTagHelper helper, ViewContext context)
    {
        helper.AppendVersion = true;
    }
}
```

To use the initializer, configure it by registering it as part of the application's startup:

C#



```
builder.Services.AddSingleton
    <ITagHelperInitializer<ScriptTagHelper>,
AppendVersionTagHelperInitializer>();
```

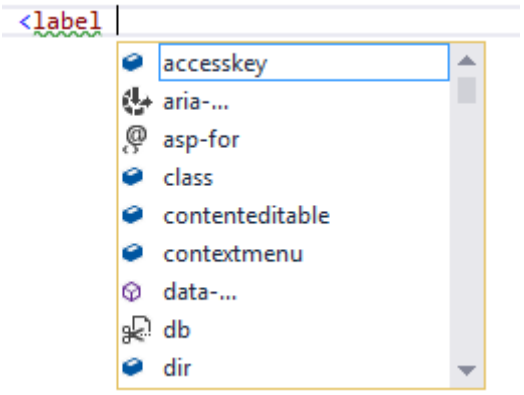
Tag Helper automatic version generation outside of wwwroot

For a Tag Helper to generate a version for a static file outside `wwwroot`, see Serve files from multiple locations

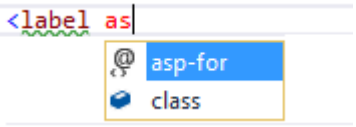
IntelliSense support for Tag Helpers

Consider writing an HTML `<label>` element. As soon as you enter `<l` in the Visual Studio editor, IntelliSense displays matching elements:

Not only do you get HTML help, but also the icon (the "@" symbol with "<>" under it).



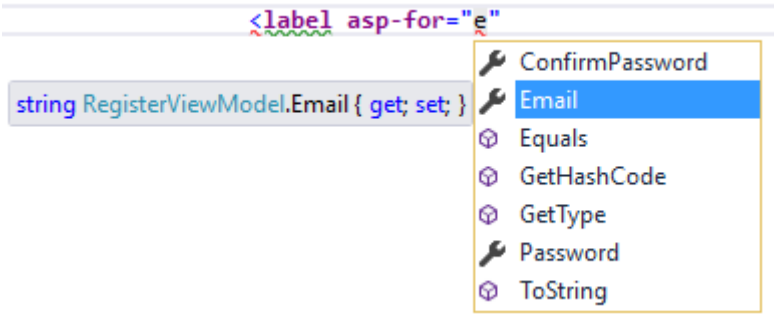
The icon identifies the element as targeted by Tag Helpers. Pure HTML elements (such as the `fieldset`) display the "<>" icon.



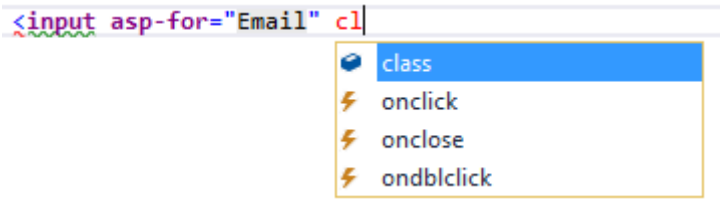
A pure HTML `<label>` tag displays the HTML tag (with the default Visual Studio color theme) in a brown font, the attributes in red, and the attribute values in blue.

```
<label class="col-md-2">Email</label>
```

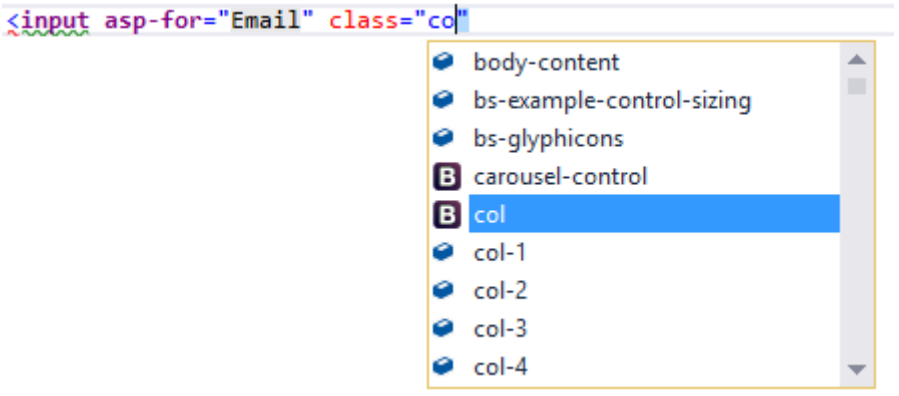
After you enter `<label`, IntelliSense lists the available HTML/CSS attributes and the Tag Helper-targeted attributes:



IntelliSense statement completion allows you to enter the tab key to complete the statement with the selected value:



As soon as a Tag Helper attribute is entered, the tag and attribute fonts change. Using the default Visual Studio "Blue" or "Light" color theme, the font is bold purple. If you're using the "Dark" theme the font is bold teal. The images in this document were taken using the default theme.



```
<label asp-for
```

You can enter the Visual Studio *CompleteWord* shortcut (Ctrl +spacebar is the default) inside the double quotes (""), and you are now in C#, just like you would be in a C# class. IntelliSense displays all the methods and properties on the page model. The methods and properties are available because the property type is `ModelExpression`. In the image below, I'm editing the `Register` view, so the `RegisterViewModel` is available.

IntelliSense lists the properties and methods available to the model on the page. The rich IntelliSense environment helps you select the CSS class:

Tag Helpers compared to HTML Helpers

Tag Helpers attach to HTML elements in Razor views, while HTML Helpers are invoked as methods interspersed with HTML in Razor views. Consider the following Razor markup, which creates an HTML label with the CSS class "caption":

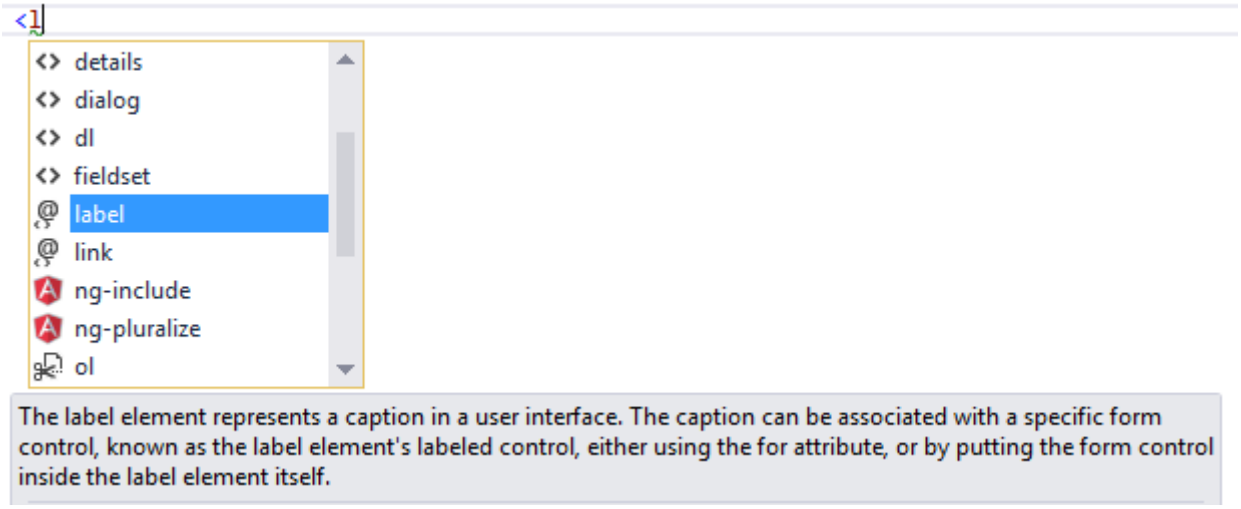
CSHTML

```
@Html.Label("FirstName", "First Name:", new {@class="caption"})
```

The at (`@`) symbol tells Razor this is the start of code. The next two parameters ("FirstName" and "First Name:") are strings, so IntelliSense can't help. The last argument:

CSHTML

```
new {@class="caption"}
```



Is an anonymous object used to represent attributes. Because `class` is a reserved keyword in C#, you use the `@` symbol to force C# to interpret `@class=` as a symbol (property name). To a front-end designer (someone familiar with HTML/CSS/JavaScript and other client technologies but not familiar with C# and Razor), most of the line is foreign. The entire line must be authored with no help from IntelliSense.

Using the `LabelTagHelper`, the same markup can be written as:

CSHTML

```
<label class="caption" asp-for="FirstName"></label>
```

With the Tag Helper version, as soon as you enter `<l` in the Visual Studio editor, IntelliSense displays matching elements:

IntelliSense helps you write the entire line.

The following code image shows the Form portion of the `Views/Account/Register.cshtml` Razor view generated from the ASP.NET 4.5.x MVC template included with Visual Studio.

```
@using (Html.BeginForm("Register", "Account", FormMethod.Post, new { @class = "form-horizo
{
    @Html.AntiForgeryToken()
    <h4>Create a new account.</h4>
    <hr />
    @Html.ValidationSummary("", new { @class = "text-danger" })
    <div class="form-group">
        @Html.LabelFor(m => m.Email, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.TextBoxFor(m => m.Email, new { @class = "form-control" })
        </div>
    </div>
    <div class="form-group">
        @Html.LabelFor(m => m.Password, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.PasswordFor(m => m.Password, new { @class = "form-control" })
        </div>
    </div>
    <div class="form-group">
        @Html.LabelFor(m => m.ConfirmPassword, new { @class = "col-md-2 control-label" })
        <div class="col-md-10">
            @Html.PasswordFor(m => m.ConfirmPassword, new { @class = "form-control" })
        </div>
    </div>
    <div class="form-group">
        <div class="col-md-offset-2 col-md-10">
            <input type="submit" class="btn btn-default" value="Register" />
        </div>
    </div>
}
```

The Visual Studio editor displays C# code with a grey background. For example, the `AntiForgeryToken` HTML Helper:

CSHTML

```
@Html.AntiForgeryToken()
```

is displayed with a grey background. Most of the markup in the Register view is C#. Compare that to the equivalent approach using Tag Helpers:

```
<form asp-controller="Account" asp-action="Register" method="post" class="form-hori
    <h4>Create a new account.</h4>
    <hr />
    <div asp-validation-summary="ValidationSummary.All" class="text-danger"></div>
    <div class="form-group">
        <label asp-for="Email" class="col-md-2 control-label"></label>
        <div class="col-md-10">
            <input asp-for="Email" class="form-control" />
            <span asp-validation-for="Email" class="text-danger"></span>
        </div>
    </div>
    <div class="form-group">
        <label asp-for="Password" class="col-md-2 control-label"></label>
        <div class="col-md-10">
            <input asp-for="Password" class="form-control" />
            <span asp-validation-for="Password" class="text-danger"></span>
        </div>
    </div>
    <div class="form-group">
        <label asp-for="ConfirmPassword" class="col-md-2 control-label"></label>
        <div class="col-md-10">
            <input asp-for="ConfirmPassword" class="form-control" />
            <span asp-validation-for="ConfirmPassword" class="text-danger"></span>
        </div>
    </div>
    <div class="form-group">
        <div class="col-md-offset-2 col-md-10">
            <button type="submit" class="btn btn-default">Register</button>
        </div>
    </div>
</form>
```

The markup is much cleaner and easier to read, edit, and maintain than the HTML Helpers approach. The C# code is reduced to the minimum that the server needs to know about. The Visual Studio editor displays markup targeted by a Tag Helper in a distinctive font.

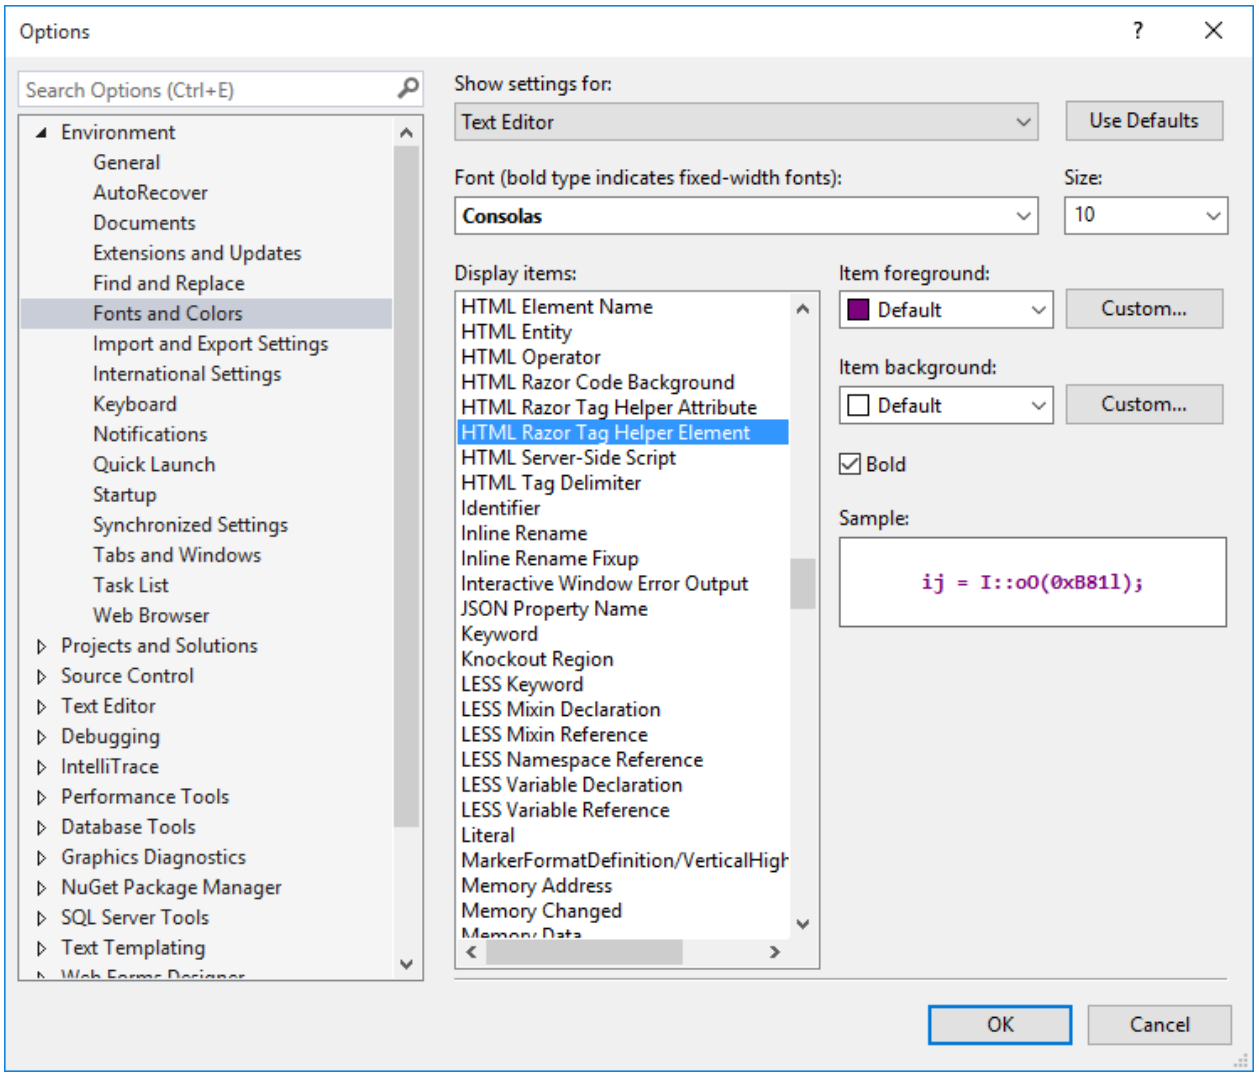
Consider the *Email* group:

CSHTML

```
<div class="form-group">
    <label asp-for="Email" class="col-md-2 control-label"></label>
    <div class="col-md-10">
        <input asp-for="Email" class="form-control" />
        <span asp-validation-for="Email" class="text-danger"></span>
    </div>
</div>
```

Each of the "asp-" attributes has a value of "Email", but "Email" isn't a string. In this context, "Email" is the C# model expression property for the `RegisterViewModel`.

The Visual Studio editor helps you write **all** of the markup in the Tag Helper approach of the register form, while Visual Studio provides no help for most of the code in the HTML



Helpers approach. IntelliSense support for Tag Helpers goes into detail on working with Tag Helpers in the Visual Studio editor.

Tag Helpers compared to Web Server Controls

- Tag Helpers don't own the element they're associated with; they simply participate in the rendering of the element and content. ASP.NET Web Server Controls are declared and invoked on a page.
- ASP.NET Web Server Controls have a non-trivial lifecycle that can make developing and debugging difficult.
- Web Server controls allow you to add functionality to the client DOM elements by using a client control. Tag Helpers have no DOM.
- Web Server controls include automatic browser detection. Tag Helpers have no knowledge of the browser.
- Multiple Tag Helpers can act on the same element (see Avoiding Tag Helper conflicts) while you typically can't compose Web Server controls.
- Tag Helpers can modify the tag and content of HTML elements that they're scoped to, but don't directly modify anything else on a page. Web Server controls have a less specific scope and can perform actions that affect other parts of your page; enabling unintended side effects.
- Web Server controls use type converters to convert strings into objects. With Tag Helpers, you work natively in C#, so you don't need to do type conversion.
- Web Server controls use System.ComponentModel to implement the run-time and design-time behavior of components and controls. `System.ComponentModel` includes the base classes and interfaces for implementing attributes and type converters, binding to data sources, and licensing components. Contrast that to Tag Helpers, which typically derive from `TagHelper`, and the `TagHelper` base class exposes only two methods, `Process` and `ProcessAsync`.

Customizing the Tag Helper element font

You can customize the font and colorization from **Tools** > **Options** > **Environment** > **Fonts and Colors**:

Author Tag Helpers in ASP.NET Core

Article • 09/14/2022

By Rick Anderson

View or download sample code (how to download)

Get started with Tag Helpers

This tutorial provides an introduction to programming Tag Helpers. Introduction to Tag Helpers describes the benefits that Tag Helpers provide.

A tag helper is any class that implements the `ITagHelper` interface. However, when you author a tag helper, you generally derive from `TagHelper`, doing so gives you access to the `Process` method.

1. Create a new ASP.NET Core project called **AuthoringTagHelpers**. You won't need authentication for this project.
2. Create a folder to hold the Tag Helpers called *TagHelpers*. The *TagHelpers* folder is *not* required, but it's a reasonable convention. Now let's get started writing some simple tag helpers.

A minimal Tag Helper

In this section, you write a tag helper that updates an email tag. For example:

HTML

```
<email>Support</email>
```

The server will use our email tag helper to convert that markup into the following:

HTML

```
<a href="mailto:Support@contoso.com">Support@contoso.com</a>
```

That is, an anchor tag that makes this an email link. You might want to do this if you are writing a blog engine and need it to send email for marketing, support, and other contacts, all to the same domain.

1. Add the following `EmailTagHelper` class to the *TagHelpers* folder.

```
C#
```

```
using Microsoft.AspNetCore.Razor.TagHelpers;
using System.Threading.Tasks;

namespace AuthoringTagHelpers.TagHelpers
{
    public class EmailTagHelper : TagHelper
    {
        public override void Process(TagHelperContext context,
TagHelperOutput output)
        {
            output.TagName = "a";    // Replaces <email> with <a> tag
        }
    }
}
```

- Tag helpers use a naming convention that targets elements of the root class name (minus the *TagHelper* portion of the class name). In this example, the root name of **EmailTagHelper** is *email*, so the `<email>` tag will be targeted. This naming convention should work for most tag helpers, later on I'll show how to override it.
- The `EmailTagHelper` class derives from `TagHelper`. The `TagHelper` class provides methods and properties for writing Tag Helpers.
- The overridden `Process` method controls what the tag helper does when executed. The `TagHelper` class also provides an asynchronous version (`ProcessAsync`) with the same parameters.
- The context parameter to `Process` (and `ProcessAsync`) contains information associated with the execution of the current HTML tag.
- The output parameter to `Process` (and `ProcessAsync`) contains a stateful HTML element representative of the original source used to generate an HTML tag and content.
- Our class name has a suffix of **TagHelper**, which is *not* required, but it's considered a best practice convention. You could declare the class as:

```
C#
```

```
public class Email : TagHelper
```

2. To make the `EmailTagHelper` class available to all our Razor views, add the `addTagHelper` directive to the `Views/_ViewImports.cshtml` file:

```
CSHTML

@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper *, AuthoringTagHelpers
```

The code above uses the wildcard syntax to specify all the tag helpers in our assembly will be available. The first string after `@addTagHelper` specifies the tag helper to load (Use "*" for all tag helpers), and the second string "AuthoringTagHelpers" specifies the assembly the tag helper is in. Also, note that the second line brings in the ASP.NET Core MVC tag helpers using the wildcard syntax (those helpers are discussed in Introduction to Tag Helpers.) It's the `@addTagHelper` directive that makes the tag helper available to the Razor view. Alternatively, you can provide the fully qualified name (FQN) of a tag helper as shown below:

```
C#

@using AuthoringTagHelpers
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@addTagHelper AuthoringTagHelpers.TagHelpers.EmailTagHelper,
AuthoringTagHelpers
```

To add a tag helper to a view using a FQN, you first add the FQN (`AuthoringTagHelpers.TagHelpers.EmailTagHelper`), and then the **assembly name** (*AuthoringTagHelpers*, not necessarily the `namespace`). Most developers will prefer to use the wildcard syntax. Introduction to Tag Helpers goes into detail on tag helper adding, removing, hierarchy, and wildcard syntax.

1. Update the markup in the `Views/Home/Contact.cshtml` file with these changes:

```
CSHTML

@{
    ViewData["Title"] = "Contact";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<address>
    One Microsoft Way<br />
    Redmond, WA 98052<br />
```

```
        <abbr title="Phone">P:</abbr>
        425.555.0100
    </address>

    <address>
        <strong>Support:</strong><email>Support</email><br />
        <strong>Marketing:</strong><email>Marketing</email>
    </address>
```

2. Run the app and use your favorite browser to view the HTML source so you can verify that the email tags are replaced with anchor markup (For example, `<a>Support</a>`). *Support* and *Marketing* are rendered as a links, but they don't have an `href` attribute to make them functional. We'll fix that in the next section.

SetAttribute and SetContent

In this section, we'll update the `EmailTagHelper` so that it will create a valid anchor tag for email. We'll update it to take information from a Razor view (in the form of a `mail-to` attribute) and use that in generating the anchor.

Update the `EmailTagHelper` class with the following:

C#

```
public class EmailTagHelper : TagHelper
{
    private const string EmailDomain = "contoso.com";

    // Can be passed via <email mail-to="..." />.
    // PascalCase gets translated into kebab-case.
    public string MailTo { get; set; }

    public override void Process(TagHelperContext context, TagHelperOutput
output)
    {
        output.TagName = "a";    // Replaces <email> with <a> tag

        var address = MailTo + "@" + EmailDomain;
        output.Attributes.SetAttribute("href", "mailto:" + address);
        output.Content.SetContent(address);
    }
}
```

- Pascal-cased class and property names for tag helpers are translated into their kebab case. Therefore, to use the `MailTo` attribute, you'll use `<email mail-to="value"/>` equivalent.

- The last line sets the completed content for our minimally functional tag helper.
- The highlighted line shows the syntax for adding attributes:

C#

```
public override void Process(TagHelperContext context, TagHelperOutput
output)
{
    output.TagName = "a";    // Replaces <email> with <a> tag

    var address = MailTo + "@" + EmailDomain;
    output.Attributes.SetAttribute("href", "mailto:" + address);
    output.Content.SetContent(address);
}
```

That approach works for the attribute "href" as long as it doesn't currently exist in the attributes collection. You can also use the `output.Attributes.Add` method to add a tag helper attribute to the end of the collection of tag attributes.

1. Update the markup in the `Views/Home/Contact.cshtml` file with these changes:

   CSHTML

   ```
   @{
       ViewData["Title"] = "Contact Copy";
   }
   <h2>@ViewData["Title"].</h2>
   <h3>@ViewData["Message"]</h3>

   <address>
       One Microsoft Way Copy Version <br />
       Redmond, WA 98052-6399<br />
       <abbr title="Phone">P:</abbr>
       425.555.0100
   </address>

   <address>
       <strong>Support:</strong><email mail-to="Support"></email><br />
       <strong>Marketing:</strong><email mail-to="Marketing"></email>
   </address>
   ```

2. Run the app and verify that it generates the correct links.

> **Note**
>
> If you were to write the email tag self-closing (`<email mail-to="Rick" />`), the final output would also be self-closing. To enable the ability to write the tag with only a

start tag (`<email mail-to="Rick">`) you must mark the class with the following:

C#

```
[HtmlTargetElement("email", TagStructure = TagStructure.WithoutEndTag)]
public class EmailVoidTagHelper : TagHelper
{
    private const string EmailDomain = "contoso.com";
    // Code removed for brevity
```

With a self-closing email tag helper, the output would be `<a href="mailto:Rick@contoso.com" />`. Self-closing anchor tags are not valid HTML, so you wouldn't want to create one, but you might want to create a tag helper that's self-closing. Tag helpers set the type of the `TagMode` property after reading a tag.

You can also map a different attribute name to a property using the [HtmlAttributeName] attribute.

To map an attribute named `recipient` to the `MailTo` property:

C#

```
[HtmlAttributeName("recipient")]
public string? MailTo { get; set; }
```

Tag Helper for the `recipient` attribute:

HTML

```
<email recipient="…"/>
```

ProcessAsync

In this section, we'll write an asynchronous email helper.

1. Replace the `EmailTagHelper` class with the following code:

   C#

   ```
   public class EmailTagHelper : TagHelper
   {
       private const string EmailDomain = "contoso.com";
       public override async Task ProcessAsync(TagHelperContext context,
   TagHelperOutput output)
   ```

```
    {
        output.TagName = "a";                                    //
Replaces <email> with <a> tag
        var content = await output.GetChildContentAsync();
        var target = content.GetContent() + "@" + EmailDomain;
        output.Attributes.SetAttribute("href", "mailto:" + target);
        output.Content.SetContent(target);
    }
}
```

Notes:

- This version uses the asynchronous `ProcessAsync` method. The asynchronous `GetChildContentAsync` returns a `Task` containing the `TagHelperContent`.
- Use the `output` parameter to get contents of the HTML element.

2. Make the following change to the `Views/Home/Contact.cshtml` file so the tag helper can get the target email.

CSHTML

```
@{
    ViewData["Title"] = "Contact";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<address>
    One Microsoft Way<br />
    Redmond, WA 98052<br />
    <abbr title="Phone">P:</abbr>
    425.555.0100
</address>

<address>
    <strong>Support:</strong><email>Support</email><br />
    <strong>Marketing:</strong><email>Marketing</email>
</address>
```

3. Run the app and verify that it generates valid email links.

RemoveAll, PreContent.SetHtmlContent and PostContent.SetHtmlContent

1. Add the following `BoldTagHelper` class to the *TagHelpers* folder.

C#

```
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace AuthoringTagHelpers.TagHelpers
{
    [HtmlTargetElement(Attributes = "bold")]
    public class BoldTagHelper : TagHelper
    {
        public override void Process(TagHelperContext context,
TagHelperOutput output)
        {
            output.Attributes.RemoveAll("bold");
            output.PreContent.SetHtmlContent("<strong>");
            output.PostContent.SetHtmlContent("</strong>");
        }
    }
}
```

- The `[HtmlTargetElement]` attribute passes an attribute parameter that specifies that any HTML element that contains an HTML attribute named "bold" will match, and the `Process` override method in the class will run. In our sample, the `Process` method removes the "bold" attribute and surrounds the containing markup with `<strong></strong>`.

- Because you don't want to replace the existing tag content, you must write the opening `<strong>` tag with the `PreContent.SetHtmlContent` method and the closing `</strong>` tag with the `PostContent.SetHtmlContent` method.

2. Modify the `About.cshtml` view to contain a `bold` attribute value. The completed code is shown below.

CSHTML

```
@{
    ViewData["Title"] = "About";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p bold>Use this area to provide additional information.</p>

<bold> Is this bold?</bold>
```

3. Run the app. You can use your favorite browser to inspect the source and verify the markup.

The `[HtmlTargetElement]` attribute above only targets HTML markup that provides an attribute name of "bold". The `<bold>` element wasn't modified by the tag helper.

4. Comment out the `[HtmlTargetElement]` attribute line and it will default to targeting `<bold>` tags, that is, HTML markup of the form `<bold>`. Remember, the default naming convention will match the class name **Bold**TagHelper to `<bold>` tags.

5. Run the app and verify that the `<bold>` tag is processed by the tag helper.

Decorating a class with multiple `[HtmlTargetElement]` attributes results in a logical-OR of the targets. For example, using the code below, a bold tag or a bold attribute will match.

C#

```
[HtmlTargetElement("bold")]
[HtmlTargetElement(Attributes = "bold")]
public class BoldTagHelper : TagHelper
{
    public override void Process(TagHelperContext context, TagHelperOutput
output)
    {
        output.Attributes.RemoveAll("bold");
        output.PreContent.SetHtmlContent("<strong>");
        output.PostContent.SetHtmlContent("</strong>");
    }
}
```

When multiple attributes are added to the same statement, the runtime treats them as a logical-AND. For example, in the code below, an HTML element must be named "bold" with an attribute named "bold" (`<bold bold />`) to match.

C#

```
[HtmlTargetElement("bold", Attributes = "bold")]
```

You can also use the `[HtmlTargetElement]` to change the name of the targeted element. For example if you wanted the `BoldTagHelper` to target `<MyBold>` tags, you would use the following attribute:

C#

```
[HtmlTargetElement("MyBold")]
```

Pass a model to a Tag Helper

1. Add a *Models* folder.

2. Add the following `WebsiteContext` class to the *Models* folder:

```
C#
```

```
using System;

namespace AuthoringTagHelpers.Models
{
    public class WebsiteContext
    {
        public Version Version { get; set; }
        public int CopyrightYear { get; set; }
        public bool Approved { get; set; }
        public int TagsToShow { get; set; }
    }
}
```

3. Add the following `WebsiteInformationTagHelper` class to the *TagHelpers* folder.

```
C#
```

```
using System;
using AuthoringTagHelpers.Models;
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace AuthoringTagHelpers.TagHelpers
{
    public class WebsiteInformationTagHelper : TagHelper
    {
        public WebsiteContext Info { get; set; }

      public override void Process(TagHelperContext context,
TagHelperOutput output)
      {
         output.TagName = "section";
         output.Content.SetHtmlContent(
$@"<ul><li><strong>Version:</strong> {Info.Version}</li>
<li><strong>Copyright Year:</strong> {Info.CopyrightYear}</li>
<li><strong>Approved:</strong> {Info.Approved}</li>
<li><strong>Number of tags to show:</strong> {Info.TagsToShow}</li>
</ul>");
         output.TagMode = TagMode.StartTagAndEndTag;
      }
   }
}
```

- As mentioned previously, tag helpers translates Pascal-cased C# class names and properties for tag helpers into kebab case. Therefore, to use the `WebsiteInformationTagHelper` in Razor, you'll write `<website-information />`.

- You are not explicitly identifying the target element with the `[HtmlTargetElement]` attribute, so the default of `website-information` will be targeted. If you applied the following attribute (note it's not kebab case but matches the class name):

```
C#

[HtmlTargetElement("WebsiteInformation")]
```

The kebab case tag `<website-information />` wouldn't match. If you want use the `[HtmlTargetElement]` attribute, you would use kebab case as shown below:

```
C#

[HtmlTargetElement("Website-Information")]
```

- Elements that are self-closing have no content. For this example, the Razor markup will use a self-closing tag, but the tag helper will be creating a section element (which isn't self-closing and you are writing content inside the `section` element). Therefore, you need to set `TagMode` to `StartTagAndEndTag` to write output. Alternatively, you can comment out the line setting `TagMode` and write markup with a closing tag. (Example markup is provided later in this tutorial.)

- The `$` (dollar sign) in the following line uses an interpolated string:

```
CSHTML

$@"<ul><li><strong>Version:</strong> {Info.Version}</li>
```

4. Add the following markup to the `About.cshtml` view. The highlighted markup displays the web site information.

```
CSHTML

@using AuthoringTagHelpers.Models
@{
    ViewData["Title"] = "About";
```

```
    WebsiteContext webContext = new WebsiteContext {
                                    Version = new Version(1, 3),
                                    CopyrightYear = 1638,
                                    Approved = true,
                                    TagsToShow = 131 };
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<p bold>Use this area to provide additional information.</p>

<bold> Is this bold?</bold>

<h3> web site info </h3>
<website-information info="webContext" />
```

> **Note**
>
> In the Razor markup shown below:
>
> ```
> HTML
> <website-information info="webContext" />
> ```
>
> Razor knows the `info` attribute is a class, not a string, and you want to write C# code. Any non-string tag helper attribute should be written without the `@` character.

5. Run the app, and navigate to the About view to see the web site information.

> **Note**
>
> You can use the following markup with a closing tag and remove the line with `TagMode.StartTagAndEndTag` in the tag helper:
>
> ```
> HTML
> <website-information info="webContext" >
> </website-information>
> ```

Condition Tag Helper

The condition tag helper renders output when passed a true value.

1. Add the following `ConditionTagHelper` class to the *TagHelpers* folder.

C#

```
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace AuthoringTagHelpers.TagHelpers
{
    [HtmlTargetElement(Attributes = nameof(Condition))]
    public class ConditionTagHelper : TagHelper
    {
        public bool Condition { get; set; }

        public override void Process(TagHelperContext context,
TagHelperOutput output)
        {
            if (!Condition)
            {
                output.SuppressOutput();
            }
        }
    }
}
```

2. Replace the contents of the `Views/Home/Index.cshtml` file with the following markup:

CSHTML

```
@using AuthoringTagHelpers.Models
@model WebsiteContext

@{
    ViewData["Title"] = "Home Page";
}

<div>
    <h3>Information about our website (outdated):</h3>
    <Website-InforMation info="Model" />
    <div condition="Model.Approved">
        <p>
            This website has <strong
surround="em">@Model.Approved</strong> been approved yet.
            Visit www.contoso.com for more information.
        </p>
    </div>
</div>
```

3. Replace the `Index` method in the `Home` controller with the following code:

C#

```
public IActionResult Index(bool approved = false)
{
    return View(new WebsiteContext
    {
        Approved = approved,
        CopyrightYear = 2015,
        Version = new Version(1, 3, 3, 7),
        TagsToShow = 20
    });
}
```

4. Run the app and browse to the home page. The markup in the conditional `div` won't be rendered. Append the query string `?approved=true` to the URL (for example, `http://localhost:1235/Home/Index?approved=true`). `approved` is set to true and the conditional markup will be displayed.

> **Note**
>
> Use the **nameof** operator to specify the attribute to target rather than specifying a string as you did with the bold tag helper:

C#

```
[HtmlTargetElement(Attributes = nameof(Condition))]
 //   [HtmlTargetElement(Attributes = "condition")]
 public class ConditionTagHelper : TagHelper
{
   public bool Condition { get; set; }

   public override void Process(TagHelperContext context,
TagHelperOutput output)
   {
      if (!Condition)
      {
         output.SuppressOutput();
      }
   }
}
```

> The **nameof** operator will protect the code should it ever be refactored (we might want to change the name to `RedCondition`).

Avoid Tag Helper conflicts

In this section, you write a pair of auto-linking tag helpers. The first will replace markup containing a URL starting with HTTP to an HTML anchor tag containing the same URL (and thus yielding a link to the URL). The second will do the same for a URL starting with WWW.

Because these two helpers are closely related and you may refactor them in the future, we'll keep them in the same file.

1. Add the following `AutoLinkerHttpTagHelper` class to the *TagHelpers* folder.

C#

```
[HtmlTargetElement("p")]
public class AutoLinkerHttpTagHelper : TagHelper
{
    public override async Task ProcessAsync(TagHelperContext context,
TagHelperOutput output)
    {
        var childContent = await output.GetChildContentAsync();
        // Find Urls in the content and replace them with their anchor
tag equivalent.
        output.Content.SetHtmlContent(Regex.Replace(
             childContent.GetContent(),
             @"\b(?:https?://)(\S+)\b",
              "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http
link version}
    }
}
```

> **Note**
>
> The `AutoLinkerHttpTagHelper` class targets `p` elements and uses **Regex** to create the anchor.

2. Add the following markup to the end of the `Views/Home/Contact.cshtml` file:

CSHTML

```
@{
    ViewData["Title"] = "Contact";
}
<h2>@ViewData["Title"].</h2>
<h3>@ViewData["Message"]</h3>

<address>
    One Microsoft Way<br />
    Redmond, WA 98052<br />
    <abbr title="Phone">P:</abbr>
```

```
    425.555.0100
</address>

<address>
    <strong>Support:</strong><email>Support</email><br />
    <strong>Marketing:</strong><email>Marketing</email>
</address>

<p>Visit us at http://docs.asp.net or at www.microsoft.com</p>
```

3. Run the app and verify that the tag helper renders the anchor correctly.

4. Update the `AutoLinker` class to include the `AutoLinkerWwwTagHelper` which will convert www text to an anchor tag that also contains the original www text. The updated code is highlighted below:

C#

```
    [HtmlTargetElement("p")]
    public class AutoLinkerHttpTagHelper : TagHelper
    {
        public override async Task ProcessAsync(TagHelperContext
context, TagHelperOutput output)
        {
            var childContent = await output.GetChildContentAsync();
            // Find Urls in the content and replace them with their
anchor tag equivalent.
            output.Content.SetHtmlContent(Regex.Replace(
                 childContent.GetContent(),
                 @"\b(?:https?://)(\S+)\b",
                  "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http
link version}
        }
    }
```

```
    [HtmlTargetElement("p")]
    public class AutoLinkerWwwTagHelper : TagHelper
    {
        public override async Task ProcessAsync(TagHelperContext
context, TagHelperOutput output)
        {
            var childContent = await output.GetChildContentAsync();
            // Find Urls in the content and replace them with their
anchor tag equivalent.
            output.Content.SetHtmlContent(Regex.Replace(
                childContent.GetContent(),
                 @"\b(www\.)(\S+)\b",
                 "<a target=\"_blank\" href=\"http://$0\">$0</a>"));
// www version
        }
    }
}
```

5. Run the app. Notice the www text is rendered as a link but the HTTP text isn't. If you put a break point in both classes, you can see that the HTTP tag helper class runs first. The problem is that the tag helper output is cached, and when the WWW tag helper is run, it overwrites the cached output from the HTTP tag helper. Later in the tutorial we'll see how to control the order that tag helpers run in. We'll fix the code with the following:

C#

```
  public class AutoLinkerHttpTagHelper : TagHelper
  {
      public override async Task ProcessAsync(TagHelperContext context,
TagHelperOutput output)
      {
          var childContent = output.Content.IsModified ?
output.Content.GetContent() :
              (await output.GetChildContentAsync()).GetContent();

          // Find Urls in the content and replace them with their
anchor tag equivalent.
          output.Content.SetHtmlContent(Regex.Replace(
               childContent,
               @"\b(?:https?://)(\S+)\b",
                "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http
link version}
      }
  }

  [HtmlTargetElement("p")]
  public class AutoLinkerWwwTagHelper : TagHelper
  {
      public override async Task ProcessAsync(TagHelperContext context,
TagHelperOutput output)
```

```
      {
          var childContent = output.Content.IsModified ?
output.Content.GetContent() :
              (await output.GetChildContentAsync()).GetContent();

          // Find Urls in the content and replace them with their
anchor tag equivalent.
          output.Content.SetHtmlContent(Regex.Replace(
               childContent,
               @"\b(www\.)(\S+)\b",
               "<a target=\"_blank\" href=\"http://$0\">$0</a>"));  //
www version
      }
  }
```

> **Note**
>
> In the first edition of the auto-linking tag helpers, you got the content of the target with the following code:
>
> C#
>
> ```
> var childContent = await output.GetChildContentAsync();
> ```
>
> That is, you call `GetChildContentAsync` using the `TagHelperOutput` passed into the `ProcessAsync` method. As mentioned previously, because the output is cached, the last tag helper to run wins. You fixed that problem with the following code:
>
> C#
>
> ```
> var childContent = output.Content.IsModified ?
> output.Content.GetContent() :
>     (await output.GetChildContentAsync()).GetContent();
> ```
>
> The code above checks to see if the content has been modified, and if it has, it gets the content from the output buffer.

6. Run the app and verify that the two links work as expected. While it might appear our auto linker tag helper is correct and complete, it has a subtle problem. If the WWW tag helper runs first, the www links won't be correct. Update the code by adding the `Order` overload to control the order that the tag runs in. The `Order` property determines the execution order relative to other tag helpers targeting the

same element. The default order value is zero and instances with lower values are executed first.

C#

```
public class AutoLinkerHttpTagHelper : TagHelper
{
    // This filter must run before the AutoLinkerWwwTagHelper as it
searches and replaces http and
    // the AutoLinkerWwwTagHelper adds http to the markup.
    public override int Order
    {
        get  {  return int.MinValue;   }
    }
```

The preceding code guarantees that the HTTP tag helper runs before the WWW tag helper. Change `Order` to `MaxValue` and verify that the markup generated for the WWW tag is incorrect.

Inspect and retrieve child content

The tag helpers provide several properties to retrieve content.

- The result of `GetChildContentAsync` can be appended to `output.Content`.
- You can inspect the result of `GetChildContentAsync` with `GetContent`.
- If you modify `output.Content`, the TagHelper body won't be executed or rendered unless you call `GetChildContentAsync` as in our auto-linker sample:

C#

```
public class AutoLinkerHttpTagHelper : TagHelper
{
    public override async Task ProcessAsync(TagHelperContext context,
TagHelperOutput output)
    {
        var childContent = output.Content.IsModified ?
output.Content.GetContent() :
            (await output.GetChildContentAsync()).GetContent();

        // Find Urls in the content and replace them with their anchor tag
equivalent.
        output.Content.SetHtmlContent(Regex.Replace(
             childContent,
             @"\b(?:https?://)(\S+)\b",
              "<a target=\"_blank\" href=\"$0\">$0</a>"));  // http link
version}
```

```
    }
}
```

- Multiple calls to `GetChildContentAsync` returns the same value and doesn't re-execute the `TagHelper` body unless you pass in a false parameter indicating not to use the cached result.

Load minified partial view TagHelper

In production environments, performance can be improved by loading minified partial views. To take advantage of minified partial view in production:

- Create/set up a pre-build process that minifies partial views.
- Use the following code to load minified partial views in non-development environments.

C#

```
public class MinifiedVersionPartialTagHelper : PartialTagHelper
    {
        public MinifiedVersionPartialTagHelper(ICompositeViewEngine
viewEngine,
                                IViewBufferScope viewBufferScope)
                               : base(viewEngine, viewBufferScope)
        {

        }

        public override Task ProcessAsync(TagHelperContext context,
TagHelperOutput output)
        {
            // Append ".min" to load the minified partial view.
            if (!IsDevelopment())
            {
                Name += ".min";
            }

            return base.ProcessAsync(context, output);
        }

        private bool IsDevelopment()
        {
            return
Environment.GetEnvironmentVariable("ASPNETCORE_ENVIRONMENT")
                                                    ==
EnvironmentName.Development;
        }
    }
```

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Tag Helper Components in ASP.NET Core

Article • 06/18/2024

By Scott Addie and Fiyaz Bin Hasan

A Tag Helper Component is a Tag Helper that allows you to conditionally modify or add HTML elements from server-side code. This feature is available in ASP.NET Core 2.0 or later.

ASP.NET Core includes two built-in Tag Helper Components: `head` and `body`. They're located in the Microsoft.AspNetCore.Mvc.Razor.TagHelpers namespace and can be used in both MVC and Razor Pages. Tag Helper Components don't require registration with the app in `_ViewImports.cshtml`.

View or download sample code (how to download)

Use cases

Two common use cases of Tag Helper Components include:

1. Injecting a <link> into the <head>.
2. Injecting a <script> into the <body>.

The following sections describe these use cases.

Inject into HTML head element

Inside the HTML `<head>` element, CSS files are commonly imported with the HTML `<link>` element. The following code injects a `<link>` element into the `<head>` element using the `head` Tag Helper Component:

C#

```
using System;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace RazorPagesSample.TagHelpers
{
    public class AddressStyleTagHelperComponent : TagHelperComponent
    {
        private readonly string _style =
```

```
            @"<link rel=""stylesheet"" href=""/css/address.css"" />";

        public override int Order => 1;

        public override Task ProcessAsync(TagHelperContext context,
                                          TagHelperOutput output)
        {
            if (string.Equals(context.TagName, "head",
                              StringComparison.OrdinalIgnoreCase))
            {
                output.PostContent.AppendHtml(_style);
            }

            return Task.CompletedTask;
        }
    }
}
```

In the preceding code:

- `AddressStyleTagHelperComponent` implements TagHelperComponent. The abstraction:
  - Allows initialization of the class with a TagHelperContext.
  - Enables the use of Tag Helper Components to add or modify HTML elements.
- The Order property defines the order in which the Components are rendered. `Order` is necessary when there are multiple usages of Tag Helper Components in an app.
- ProcessAsync compares the execution context's TagName property value to `head`. If the comparison evaluates to true, the content of the `_style` field is injected into the HTML `<head>` element.

Inject into HTML body element

The `body` Tag Helper Component can inject a `<script>` element into the `<body>` element. The following code demonstrates this technique:

C#

```
using System;
using System.IO;
using System.Threading.Tasks;
using Microsoft.AspNetCore.Razor.TagHelpers;

namespace RazorPagesSample.TagHelpers
{
    public class AddressScriptTagHelperComponent : TagHelperComponent
    {
```

```
        public override int Order => 2;

        public override async Task ProcessAsync(TagHelperContext context,
                                                TagHelperOutput output)
        {
            if (string.Equals(context.TagName, "body",
                              StringComparison.OrdinalIgnoreCase))
            {
                var script = await File.ReadAllTextAsync(
                    "TagHelpers/Templates/AddressToolTipScript.html");
                output.PostContent.AppendHtml(script);
            }
        }
    }
}
```

A separate HTML file is used to store the `<script>` element. The HTML file makes the code cleaner and more maintainable. The preceding code reads the contents of `TagHelpers/Templates/AddressToolTipScript.html` and appends it with the Tag Helper output. The `AddressToolTipScript.html` file includes the following markup:

HTML

```
<script>
$("address[printable]").hover(function() {
    $(this).attr({
        "data-toggle": "tooltip",
        "data-placement": "right",
        "title": "Home of Microsoft!"
    });
});
</script>
```

The preceding code binds a Bootstrap tooltip widget to any `<address>` element that includes a `printable` attribute. The effect is visible when a mouse pointer hovers over the element.

Register a Component

A Tag Helper Component must be added to the app's Tag Helper Components collection. There are three ways to add to the collection:

- Registration via services container
- Registration via Razor file
- Registration via Page Model or controller

Registration via services container

If the Tag Helper Component class isn't managed with ITagHelperComponentManager, it must be registered with the dependency injection (DI) system. The following `Startup.ConfigureServices` code registers the `AddressStyleTagHelperComponent` and `AddressScriptTagHelperComponent` classes with a transient lifetime:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.Configure<CookiePolicyOptions>(options =>
    {
        options.CheckConsentNeeded = context => true;
        options.MinimumSameSitePolicy = SameSiteMode.None;
    });

    services.AddMvc()
            .SetCompatibilityVersion(CompatibilityVersion.Version_2_1);

    services.AddTransient<ITagHelperComponent,
        AddressScriptTagHelperComponent>();
    services.AddTransient<ITagHelperComponent,
        AddressStyleTagHelperComponent>();
}
```

Registration via Razor file

If the Tag Helper Component isn't registered with DI, it can be registered from a Razor Pages page or an MVC view. This technique is used for controlling the injected markup and the component execution order from a Razor file.

`ITagHelperComponentManager` is used to add Tag Helper Components or remove them from the app. The following code demonstrates this technique with `AddressTagHelperComponent`:

CSHTML

```
@using RazorPagesSample.TagHelpers;
@using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
@inject ITagHelperComponentManager manager;

@{
    string markup;

    if (Model.IsWeekend)
    {
        markup = "<em class='text-warning'>Office closed today!</em>";
```

```
    }
    else
    {
        markup = "<em class='text-info'>Office open today!</em>";
    }

    manager.Components.Add(new AddressTagHelperComponent(markup, 1));
}
```

In the preceding code:

- The `@inject` directive provides an instance of `ITagHelperComponentManager`. The instance is assigned to a variable named `manager` for access downstream in the Razor file.
- An instance of `AddressTagHelperComponent` is added to the app's Tag Helper Components collection.

`AddressTagHelperComponent` is modified to accommodate a constructor that accepts the `markup` and `order` parameters:

C#

```
private readonly string _markup;

public override int Order { get; }

public AddressTagHelperComponent(string markup = "", int order = 1)
{
    _markup = markup;
    Order = order;
}
```

The provided `markup` parameter is used in `ProcessAsync` as follows:

C#

```
public override async Task ProcessAsync(TagHelperContext context,
                                        TagHelperOutput output)
{
    if (string.Equals(context.TagName, "address",
            StringComparison.OrdinalIgnoreCase) &&
        output.Attributes.ContainsName("printable"))
    {
        TagHelperContent childContent = await output.GetChildContentAsync();
        string content = childContent.GetContent();
        output.Content.SetHtmlContent(
            $"<div>{content}<br>{_markup}</div>{_printableButton}");
```

```
    }
}
```

Registration via Page Model or controller

If the Tag Helper Component isn't registered with DI, it can be registered from a Razor Pages page model or an MVC controller. This technique is useful for separating C# logic from Razor files.

Constructor injection is used to access an instance of `ITagHelperComponentManager`. The Tag Helper Component is added to the instance's Tag Helper Components collection. The following Razor Pages page model demonstrates this technique with `AddressTagHelperComponent`:

C#

```
using System;
using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
using Microsoft.AspNetCore.Mvc.RazorPages;
using RazorPagesSample.TagHelpers;

public class IndexModel : PageModel
{
    private readonly ITagHelperComponentManager _tagHelperComponentManager;

    public bool IsWeekend
    {
        get
        {
            var dayOfWeek = DateTime.Now.DayOfWeek;

            return dayOfWeek == DayOfWeek.Saturday ||
                   dayOfWeek == DayOfWeek.Sunday;
        }
    }

    public IndexModel(ITagHelperComponentManager tagHelperComponentManager)
    {
        _tagHelperComponentManager = tagHelperComponentManager;
    }

    public void OnGet()
    {
        string markup;

        if (IsWeekend)
        {
            markup = "<em class='text-warning'>Office closed today!</em>";
        }
        else
```

```
        {
            markup = "<em class='text-info'>Office open today!</em>";
        }

        _tagHelperComponentManager.Components.Add(
            new AddressTagHelperComponent(markup, 1));
    }
}
```

In the preceding code:

- Constructor injection is used to access an instance of `ITagHelperComponentManager`.
- An instance of `AddressTagHelperComponent` is added to the app's Tag Helper Components collection.

Create a Component

To create a custom Tag Helper Component:

- Create a public class deriving from TagHelperComponentTagHelper.
- Apply an [HtmlTargetElement] attribute to the class. Specify the name of the target HTML element.
- *Optional*: Apply an [EditorBrowsable(EditorBrowsableState.Never)] attribute to the class to suppress the type's display in IntelliSense.

The following code creates a custom Tag Helper Component that targets the `<address>` HTML element:

C#

```
using System.ComponentModel;
using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
using Microsoft.AspNetCore.Razor.TagHelpers;
using Microsoft.Extensions.Logging;

namespace RazorPagesSample.TagHelpers
{
    [HtmlTargetElement("address")]
    [EditorBrowsable(EditorBrowsableState.Never)]
    public class AddressTagHelperComponentTagHelper :
TagHelperComponentTagHelper
    {
        public AddressTagHelperComponentTagHelper(
            ITagHelperComponentManager componentManager,
            ILoggerFactory loggerFactory) : base(componentManager,
loggerFactory)
        {
        }
```

```
    }
}
```

Use the custom `address` Tag Helper Component to inject HTML markup as follows:

C#

```
public class AddressTagHelperComponent : TagHelperComponent
{
    private readonly string _printableButton =
        "<button type='button' class='btn btn-info' onclick=\"window.open("
+
        "'https://binged.it/2AXRRYw')\">" +
        "<span class='glyphicon glyphicon-road' aria-hidden='true'></span>"
+
        "</button>";

    public override int Order => 3;

    public override async Task ProcessAsync(TagHelperContext context,
                                            TagHelperOutput output)
    {
        if (string.Equals(context.TagName, "address",
                StringComparison.OrdinalIgnoreCase) &&
            output.Attributes.ContainsName("printable"))
        {
            var content = await output.GetChildContentAsync();
            output.Content.SetHtmlContent(
                $"<div>{content.GetContent()}</div>{_printableButton}");
        }
    }
}
```

The preceding `ProcessAsync` method injects the HTML provided to SetHtmlContent into the matching `<address>` element. The injection occurs when:

- The execution context's `TagName` property value equals `address`.
- The corresponding `<address>` element has a `printable` attribute.

For example, the `if` statement evaluates to true when processing the following `<address>` element:

CSHTML

```
<address printable>
    One Microsoft Way<br />
    Redmond, WA 98052-6399<br />
    <abbr title="Phone">P:</abbr>
```

```
    425.555.0100
</address>
```

Anchor Tag Helper in ASP.NET Core

Article • 06/18/2024

By Peter Kellner and Scott Addie

The Anchor Tag Helper enhances the standard HTML anchor (`<a ... ></a>`) tag by adding new attributes. By convention, the attribute names are prefixed with `asp-`. The rendered anchor element's `href` attribute value is determined by the values of the `asp-` attributes.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

View or download sample code (how to download)

SpeakerController is used in samples throughout this document:

C#

```
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;
using System.Linq;

public class SpeakerController : Controller
{
    private List<Speaker> Speakers =
        new List<Speaker>
        {
            new Speaker {SpeakerId = 10},
            new Speaker {SpeakerId = 11},
            new Speaker {SpeakerId = 12}
        };

    [Route("Speaker/{id:int}")]
    public IActionResult Detail(int id) =>
        View(Speakers.FirstOrDefault(a => a.SpeakerId == id));

    [Route("/Speaker/Evaluations",
           Name = "speakerevals")]
    public IActionResult Evaluations() => View();

    [Route("/Speaker/EvaluationsCurrent",
           Name = "speakerevalscurrent")]
    public IActionResult Evaluations(
        int speakerId,
        bool currentYear) => View();

    public IActionResult Index() => View(Speakers);
}

public class Speaker
```

```
{
    public int SpeakerId { get; set; }
}
```

Anchor Tag Helper attributes

asp-controller

The asp-controller attribute assigns the controller used for generating the URL. The following markup lists all speakers:

CSHTML

```
<a asp-controller="Speaker"
   asp-action="Index">All Speakers</a>
```

The generated HTML:

HTML

```
<a href="/Speaker">All Speakers</a>
```

If the `asp-controller` attribute is specified and `asp-action` isn't, the default `asp-action` value is the controller action associated with the currently executing view. If `asp-action` is omitted from the preceding markup, and the Anchor Tag Helper is used in *HomeController*'s *Index* view (*/Home*), the generated HTML is:

HTML

```
<a href="/Home">All Speakers</a>
```

asp-action

The asp-action attribute value represents the controller action name included in the generated `href` attribute. The following markup sets the generated `href` attribute value to the speaker evaluations page:

CSHTML

```
<a asp-controller="Speaker"
   asp-action="Evaluations">Speaker Evaluations</a>
```

The generated HTML:

```HTML
<a href="/Speaker/Evaluations">Speaker Evaluations</a>
```

If no `asp-controller` attribute is specified, the default controller calling the view executing the current view is used.

If the `asp-action` attribute value is `Index`, then no action is appended to the URL, leading to the invocation of the default `Index` action. The action specified (or defaulted), must exist in the controller referenced in `asp-controller`.

asp-route-{value}

The asp-route-{value} attribute enables a wildcard route prefix. Any value occupying the `{value}` placeholder is interpreted as a potential route parameter. If a default route isn't found, this route prefix is appended to the generated `href` attribute as a request parameter and value. Otherwise, it's substituted in the route template.

Consider the following controller action:

```C#
private List<Speaker> Speakers =
    new List<Speaker>
    {
        new Speaker {SpeakerId = 10},
        new Speaker {SpeakerId = 11},
        new Speaker {SpeakerId = 12}
    };

[Route("Speaker/{id:int}")]
public IActionResult Detail(int id) =>
    View(Speakers.FirstOrDefault(a => a.SpeakerId == id));
```

With a default route template defined in *Startup.Configure*:

```C#
app.UseMvc(routes =>
{
    // need route and attribute on controller: [Area("Blogs")]
    routes.MapRoute(name: "mvcAreaRoute",
                    template: "
{area:exists}/{controller=Home}/{action=Index}");
```

```
    // default route for non-areas
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

The MVC view uses the model, provided by the action, as follows:

CSHTML

```
@model Speaker
<!DOCTYPE html>
<html>
<body>
    <a asp-controller="Speaker"
       asp-action="Detail"
       asp-route-id="@Model.SpeakerId">SpeakerId: @Model.SpeakerId</a>
</body>
</html>
```

The default route's `{id?}` placeholder was matched. The generated HTML:

HTML

```
<a href="/Speaker/Detail/12">SpeakerId: 12</a>
```

Assume the route prefix isn't part of the matching routing template, as with the following MVC view:

CSHTML

```
@model Speaker
<!DOCTYPE html>
<html>
<body>
    <a asp-controller="Speaker"
       asp-action="Detail"
       asp-route-speakerid="@Model.SpeakerId">SpeakerId:
@Model.SpeakerId</a>
<body>
</html>
```

The following HTML is generated because `speakerid` wasn't found in the matching route:

HTML

```
<a href="/Speaker/Detail?speakerid=12">SpeakerId: 12</a>
```

If either `asp-controller` or `asp-action` aren't specified, then the same default processing is followed as is in the `asp-route` attribute.

asp-route

The asp-route attribute is used for creating a URL linking directly to a named route. Using routing attributes, a route can be named as shown in the `SpeakerController` and used in its `Evaluations` action:

C#

```
[Route("/Speaker/Evaluations",
       Name = "speakerevals")]
```

In the following markup, the `asp-route` attribute references the named route:

CSHTML

```
<a asp-route="speakerevals">Speaker Evaluations</a>
```

The Anchor Tag Helper generates a route directly to that controller action using the URL */Speaker/Evaluations*. The generated HTML:

HTML

```
<a href="/Speaker/Evaluations">Speaker Evaluations</a>
```

If `asp-controller` or `asp-action` is specified in addition to `asp-route`, the route generated may not be what you expect. To avoid a route conflict, `asp-route` shouldn't be used with the `asp-controller` and `asp-action` attributes.

asp-all-route-data

The asp-all-route-data attribute supports the creation of a dictionary of key-value pairs. The key is the parameter name, and the value is the parameter value.

In the following example, a dictionary is initialized and passed to a Razor view. Alternatively, the data could be passed in with your model.

CSHTML

```
@{
var parms = new Dictionary<string, string>
            {
                { "speakerId", "11" },
                { "currentYear", "true" }
            };
}

<a asp-route="speakerevalscurrent"
   asp-all-route-data="parms">Speaker Evaluations</a>
```

The preceding code generates the following HTML:

HTML

```
<a href="/Speaker/EvaluationsCurrent?speakerId=11&currentYear=true">Speaker
Evaluations</a>
```

The `asp-all-route-data` dictionary is flattened to produce a querystring meeting the requirements of the overloaded `Evaluations` action:

C#

```
public IActionResult Evaluations() => View();

[Route("/Speaker/EvaluationsCurrent",
       Name = "speakerevalscurrent")]
public IActionResult Evaluations(
```

If any keys in the dictionary match route parameters, those values are substituted in the route as appropriate. The other non-matching values are generated as request parameters.

asp-fragment

The asp-fragment attribute defines a URL fragment to append to the URL. The Anchor Tag Helper adds the hash character (#). Consider the following markup:

CSHTML

```
<a asp-controller="Speaker"
   asp-action="Evaluations"
   asp-fragment="SpeakerEvaluations">Speaker Evaluations</a>
```

The generated HTML:

```HTML
<a href="/Speaker/Evaluations#SpeakerEvaluations">Speaker Evaluations</a>
```

Hash tags are useful when building client-side apps. They can be used for easy marking and searching in JavaScript, for example.

asp-area

The asp-area attribute sets the area name used to set the appropriate route. The following examples depict how the `asp-area` attribute causes a remapping of routes.

Usage in Razor Pages

Razor Pages areas are supported in ASP.NET Core 2.1 or later.

Consider the following directory hierarchy:

- **{Project name}**
  - **wwwroot**
  - **Areas**
    - **Sessions**
      - **Pages**
        - *_ViewStart.cshtml*
        - `Index.cshtml`
        - `Index.cshtml.cs`
  - **Pages**

The markup to reference the *Sessions* area *Index* Razor Page is:

```CSHTML
<a asp-area="Sessions"
   asp-page="/Index">View Sessions</a>
```

The generated HTML:

```HTML
<a href="/Sessions">View Sessions</a>
```

> **Tip**
>
> To support areas in a Razor Pages app, do one of the following in `Startup.ConfigureServices`:
>
> - Set the compatibility version to 2.1 or later.
> - Set the RazorPagesOptions.AllowAreas property to `true`:
>
> ```
> C#
> ```
>
> ```
> services.AddMvc()
>         .AddRazorPagesOptions(options => options.AllowAreas =
> true);
> ```

Usage in MVC

Consider the following directory hierarchy:

- **{Project name}**
  - **wwwroot**
  - **Areas**
    - **Blogs**
      - **Controllers**
        - `HomeController.cs`
      - **Views**
        - **Home**
          - `AboutBlog.cshtml`
          - `Index.cshtml`
        - *_ViewStart.cshtml*
  - **Controllers**

Setting `asp-area` to "Blogs" prefixes the directory *Areas/Blogs* to the routes of the associated controllers and views for this anchor tag. The markup to reference the *AboutBlog* view is:

```
CSHTML
```

```
<a asp-area="Blogs"
   asp-controller="Home"
   asp-action="AboutBlog">About Blog</a>
```

The generated HTML:

```HTML
<a href="/Blogs/Home/AboutBlog">About Blog</a>
```

> **Tip**
>
> To support areas in an MVC app, the route template must include a reference to the area, if it exists. That template is represented by the second parameter of the `routes.MapRoute` method call in *Startup.Configure*:

```C#
app.UseMvc(routes =>
{
    // need route and attribute on controller: [Area("Blogs")]
    routes.MapRoute(name: "mvcAreaRoute",
                    template: "
{area:exists}/{controller=Home}/{action=Index}");

    // default route for non-areas
    routes.MapRoute(
        name: "default",
        template: "{controller=Home}/{action=Index}/{id?}");
});
```

asp-protocol

The asp-protocol attribute is for specifying a protocol (such as `https`) in your URL. For example:

```CSHTML
<a asp-protocol="https"
   asp-controller="Home"
   asp-action="About">About</a>
```

The generated HTML:

```HTML
<a href="https://localhost/Home/About">About</a>
```

The host name in the example is localhost. The Anchor Tag Helper uses the website's public domain when generating the URL.

asp-host

The asp-host attribute is for specifying a host name in your URL. For example:

CSHTML

```
<a asp-protocol="https"
   asp-host="microsoft.com"
   asp-controller="Home"
   asp-action="About">About</a>
```

The generated HTML:

HTML

```
<a href="https://microsoft.com/Home/About">About</a>
```

asp-page

The asp-page attribute is used with Razor Pages. Use it to set an anchor tag's `href` attribute value to a specific page. Prefixing the page name with `/` creates a URL for a matching page from the root of the app:

With the sample code, the following markup creates a link to the attendee Razor Page:

CSHTML

```
<a asp-page="/Attendee">All Attendees</a>
```

The generated HTML:

HTML

```
<a href="/Attendee">All Attendees</a>
```

The `asp-page` attribute is mutually exclusive with the `asp-route`, `asp-controller`, and `asp-action` attributes. However, `asp-page` can be used with `asp-route-{value}` to control routing, as the following markup demonstrates:

CSHTML

```
<a asp-page="/Attendee"
   asp-route-attendeeid="10">View Attendee</a>
```

The generated HTML:

HTML

```
<a href="/Attendee?attendeeid=10">View Attendee</a>
```

If the referenced page doesn't exist, a link to the current page is generated using an ambient value from the request. No warning is indicated, except at the debug log level.

asp-page-handler

The asp-page-handler attribute is used with Razor Pages. It's intended for linking to specific page handlers.

Consider the following page handler:

C#

```
public void OnGetProfile(int attendeeId)
{
    ViewData["AttendeeId"] = attendeeId;

    // code omitted for brevity
}
```

The page model's associated markup links to the `OnGetProfile` page handler. Note the `On<Verb>` prefix of the page handler method name is omitted in the `asp-page-handler` attribute value. When the method is asynchronous, the `Async` suffix is omitted, too.

CSHTML

```
<a asp-page="/Attendee"
   asp-page-handler="Profile"
   asp-route-attendeeid="12">Attendee Profile</a>
```

The generated HTML:

HTML

```
<a href="/Attendee?attendeeid=12&handler=Profile">Attendee Profile</a>
```

Cache Tag Helper in ASP.NET Core MVC

Article • 06/17/2024

By Peter Kellner

The Cache Tag Helper provides the ability to improve the performance of your ASP.NET Core app by caching its content to the internal ASP.NET Core cache provider.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

The following Razor markup caches the current date:

```cshtml
<cache>@DateTime.Now</cache>
```

The first request to the page that contains the Tag Helper displays the current date. Additional requests show the cached value until the cache expires (default 20 minutes) or until the cached date is evicted from the cache.

Cache Tag Helper Attributes

enabled

Expand table

Attribute Type	Examples	Default
Boolean	`true`, `false`	`true`

`enabled` determines if the content enclosed by the Cache Tag Helper is cached. The default is `true`. If set to `false`, the rendered output is **not** cached.

Example:

```cshtml
<cache enabled="true">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

expires-on

Expand table

Attribute Type	Example
`DateTimeOffset`	`@new DateTime(2025,1,29,17,02,0)`

`expires-on` sets an absolute expiration date for the cached item.

The following example caches the contents of the Cache Tag Helper until 5:02 PM on January 29, 2025:

CSHTML

```
<cache expires-on="@new DateTime(2025,1,29,17,02,0)">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

expires-after

Expand table

Attribute Type	Example	Default
`TimeSpan`	`@TimeSpan.FromSeconds(120)`	20 minutes

`expires-after` sets the length of time from the first request time to cache the contents.

Example:

CSHTML

```
<cache expires-after="@TimeSpan.FromSeconds(120)">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

The Razor View Engine sets the default `expires-after` value to twenty minutes.

expires-sliding

Expand table

Attribute Type	Example
`TimeSpan`	`@TimeSpan.FromSeconds(60)`

Sets the time that a cache entry should be evicted if its value hasn't been accessed.

Example:

CSHTML

```
<cache expires-sliding="@TimeSpan.FromSeconds(60)">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-header

Expand table

Attribute Type	Examples
String	`User-Agent`, `User-Agent,content-encoding`

`vary-by-header` accepts a comma-delimited list of header values that trigger a cache refresh when they change.

The following example monitors the header value `User-Agent`. The example caches the content for every different `User-Agent` presented to the web server:

CSHTML

```
<cache vary-by-header="User-Agent">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-query

Expand table

Attribute Type	Examples
String	`Make`, `Make,Model`

`vary-by-query` accepts a comma-delimited list of Keys in a query string (Query) that trigger a cache refresh when the value of any listed key changes.

The following example monitors the values of `Make` and `Model`. The example caches the content for every different `Make` and `Model` presented to the web server:

CSHTML

```
<cache vary-by-query="Make,Model">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-route

Expand table

Attribute Type	Examples
String	`Make`, `Make,Model`

`vary-by-route` accepts a comma-delimited list of route parameter names that trigger a cache refresh when the route data parameter value changes.

Example:

`Startup.cs`:

C#

```
routes.MapRoute(
    name: "default",
    template: "{controller=Home}/{action=Index}/{Make?}/{Model?}");
```

`Index.cshtml`:

CSHTML

```
<cache vary-by-route="Make,Model">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-cookie

Expand table

Attribute Type	Examples
String	`.AspNetCore.Identity.Application`, `.AspNetCore.Identity.Application,HairColor`

`vary-by-cookie` accepts a comma-delimited list of cookie names that trigger a cache refresh when the cookie values change.

The following example monitors the cookie associated with ASP.NET Core Identity. When a user is authenticated, a change in the Identity cookie triggers a cache refresh:

CSHTML

```
<cache vary-by-cookie=".AspNetCore.Identity.Application">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

vary-by-user

Expand table

Attribute Type	Examples	Default
Boolean	`true`, `false`	`true`

`vary-by-user` specifies whether or not the cache resets when the signed-in user (or Context Principal) changes. The current user is also known as the Request Context Principal and can be viewed in a Razor view by referencing `@User.Identity.Name`.

The following example monitors the current logged in user to trigger a cache refresh:

CSHTML

```
<cache vary-by-user="true">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

Using this attribute maintains the contents in cache through a sign-in and sign-out cycle. When the value is set to `true`, an authentication cycle invalidates the cache for the authenticated user. The cache is invalidated because a new unique cookie value is generated when a user is authenticated. Cache is maintained for the anonymous state

when no cookie is present or the cookie has expired. If the user is **not** authenticated, the cache is maintained.

vary-by

Expand table

Attribute Type	Example
String	`@Model`

`vary-by` allows for customization of what data is cached. When the object referenced by the attribute's string value changes, the content of the Cache Tag Helper is updated. Often, a string-concatenation of model values are assigned to this attribute. Effectively, this results in a scenario where an update to any of the concatenated values invalidates the cache.

The following example assumes the controller method rendering the view sums the integer value of the two route parameters, `myParam1` and `myParam2`, and returns the sum as the single model property. When this sum changes, the content of the Cache Tag Helper is rendered and cached again.

Action:

C#

```
public IActionResult Index(string myParam1, string myParam2, string
myParam3)
{
    int num1;
    int num2;
    int.TryParse(myParam1, out num1);
    int.TryParse(myParam2, out num2);
    return View(viewName, num1 + num2);
}
```

`Index.cshtml`:

CSHTML

```
<cache vary-by="@Model">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

priority

Expand table

Attribute Type	Examples	Default
`CacheItemPriority`	`High`, `Low`, `NeverRemove`, `Normal`	`Normal`

`priority` provides cache eviction guidance to the built-in cache provider. The web server evicts `Low` cache entries first when it's under memory pressure.

Example:

CSHTML

```
<cache priority="High">
    Current Time Inside Cache Tag Helper: @DateTime.Now
</cache>
```

The `priority` attribute doesn't guarantee a specific level of cache retention. `CacheItemPriority` is only a suggestion. Setting this attribute to `NeverRemove` doesn't guarantee that cached items are always retained. See the topics in the Additional Resources section for more information.

The Cache Tag Helper is dependent on the memory cache service. The Cache Tag Helper adds the service if it hasn't been added.

Component Tag Helper in ASP.NET Core

Article • 10/02/2023

The Component Tag Helper renders a Razor component in a Razor Pages page or MVC view.

Prerequisites

Follow the guidance in the *Use non-routable components in pages or views* section of the Integrate ASP.NET Core Razor components into ASP.NET Core apps article.

Component Tag Helper

To render a component from a page or view, use the Component Tag Helper (`<component>` tag).

RenderMode configures whether the component:

- Is prerendered into the page.
- Is rendered as static HTML on the page or if it includes the necessary information to bootstrap a Blazor app from the user agent.

Blazor WebAssembly app render modes are shown in the following table.

Expand table

Render Mode	Description
`WebAssembly`	Renders a marker for a Blazor WebAssembly app for use to include an interactive component when loaded in the browser. The component isn't prerendered. This option makes it easier to render different Blazor WebAssembly components on different pages.
`WebAssemblyPrerendered`	Prerenders the component into static HTML and includes a marker for a Blazor WebAssembly app for later use to make the component interactive when loaded in the browser.

Render modes are shown in the following table.

Expand table

Render Mode	Description
ServerPrerendered	Renders the component into static HTML and includes a marker for a server-side Blazor app. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Server	Renders a marker for a server-side Blazor app. Output from the component isn't included. When the user-agent starts, this marker is used to bootstrap a Blazor app.
Static	Renders the component into static HTML.

Additional characteristics include:

- Multiple Component Tag Helpers rendering multiple Razor components is allowed.
- Components can't be dynamically rendered after the app has started.
- While pages and views can use components, the converse isn't true. Components can't use view- and page-specific features, such as partial views and sections. To use logic from a partial view in a component, factor out the partial view logic into a component.
- Rendering server components from a static HTML page isn't supported.

The following Component Tag Helper renders the `EmbeddedCounter` component in a page or view in a server-side Blazor app with `ServerPrerendered`:

CSHTML

```
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using {APP ASSEMBLY}.Components

...

<component type="typeof(EmbeddedCounter)" render-mode="ServerPrerendered" />
```

The preceding example assumes that the `EmbeddedCounter` component is in the app's `Components` folder. The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `@using BlazorSample.Components`).

The Component Tag Helper can also pass parameters to components. Consider the following `ColorfulCheckbox` component that sets the checkbox label's color and size.

`Components/ColorfulCheckbox.razor`:

razor

```
<label style="font-size:@(Size)px;color:@Color">
    <input @bind="Value"
           id="survey"
           name="blazor"
           type="checkbox" />
    Enjoying Blazor?
</label>

@code {
    [Parameter]
    public bool Value { get; set; }

    [Parameter]
    public int Size { get; set; } = 8;

    [Parameter]
    public string? Color { get; set; }

    protected override void OnInitialized()
    {
        Size += 10;
    }
}
```

The `Size` (`int`) and `Color` (`string`) component parameters can be set by the Component Tag Helper:

CSHTML

```
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using {APP ASSEMBLY}.Components

...

<component type="typeof(ColorfulCheckbox)" render-mode="ServerPrerendered"
    param-Size="14" param-Color="@("blue")" />
```

The preceding example assumes that the `ColorfulCheckbox` component is in the `Components` folder. The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `@using BlazorSample.Components`).

The following HTML is rendered in the page or view:

HTML

```
<label style="font-size:24px;color:blue">
    <input id="survey" name="blazor" type="checkbox">
```

```
    Enjoying Blazor?
</label>
```

Passing a quoted string requires an explicit Razor expression, as shown for `param-Color` in the preceding example. The Razor parsing behavior for a `string` type value doesn't apply to a `param-*` attribute because the attribute is an `object` type.

All types of parameters are supported, except:

- Generic parameters.
- Non-serializable parameters.
- Inheritance in collection parameters.
- Parameters whose type is defined outside of the Blazor WebAssembly app or within a lazily-loaded assembly.
- For receiving a RenderFragment delegate for child content (for example, `param-ChildContent="..."`). For this scenario, we recommend creating a Razor component (`.razor`) that references the component you want to render with the child content you want to pass and then invoke the Razor component from the page or view with the Component Tag Helper.

The parameter type must be JSON serializable, which typically means that the type must have a default constructor and settable properties. For example, you can specify a value for `Size` and `Color` in the preceding example because the types of `Size` and `Color` are primitive types (`int` and `string`), which are supported by the JSON serializer.

In the following example, a class object is passed to the component:

`MyClass.cs`:

C#

```
public class MyClass
{
    public MyClass()
    {
    }

    public int MyInt { get; set; } = 999;
    public string MyString { get; set; } = "Initial value";
}
```

The class must have a public parameterless constructor.

`Components/ParameterComponent.razor`:

razor

```razor
<h2>ParameterComponent</h2>

<p>Int: @MyObject?.MyInt</p>
<p>String: @MyObject?.MyString</p>

@code
{
    [Parameter]
    public MyClass? MyObject { get; set; }
}
```

`Pages/MyPage.cshtml`:

CSHTML

```cshtml
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@using {APP ASSEMBLY}
@using {APP ASSEMBLY}.Components

...

@{
    var myObject = new MyClass();
    myObject.MyInt = 7;
    myObject.MyString = "Set by MyPage";
}

<component type="typeof(ParameterComponent)" render-mode="ServerPrerendered"
    param-MyObject="@myObject" />
```

The preceding example assumes that the `ParameterComponent` component is in the app's `Components` folder. The placeholder `{APP ASSEMBLY}` is the app's assembly name (for example, `@using BlazorSample` and `@using BlazorSample.Components`). `MyClass` is in the app's namespace.

Distributed Cache Tag Helper in ASP.NET Core

Article • 06/17/2024

By Peter Kellner

The Distributed Cache Tag Helper provides the ability to dramatically improve the performance of your ASP.NET Core app by caching its content to a distributed cache source.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

The Distributed Cache Tag Helper inherits from the same base class as the Cache Tag Helper. All of the Cache Tag Helper attributes are available to the Distributed Tag Helper.

The Distributed Cache Tag Helper uses constructor injection. The IDistributedCache interface is passed into the Distributed Cache Tag Helper's constructor. If no concrete implementation of `IDistributedCache` is created in `Startup.ConfigureServices` (`Startup.cs`), the Distributed Cache Tag Helper uses the same in-memory provider for storing cached data as the Cache Tag Helper.

Distributed Cache Tag Helper Attributes

Attributes shared with the Cache Tag Helper

- `enabled`
- `expires-on`
- `expires-after`
- `expires-sliding`
- `vary-by-header`
- `vary-by-query`
- `vary-by-route`
- `vary-by-cookie`
- `vary-by-user`
- `vary-by`
- `priority`

The Distributed Cache Tag Helper inherits from the same class as Cache Tag Helper. For descriptions of these attributes, see the Cache Tag Helper.

name

Expand table

Attribute Type	Example
String	`my-distributed-cache-unique-key-101`

`name` is required. The `name` attribute is used as a key for each stored cache instance. Unlike the Cache Tag Helper that assigns a cache key to each instance based on the Razor page name and location in the Razor page, the Distributed Cache Tag Helper only bases its key on the attribute `name`.

Example:

CSHTML

```
<distributed-cache name="my-distributed-cache-unique-key-101">
    Time Inside Cache Tag Helper: @DateTime.Now
</distributed-cache>
```

Distributed Cache Tag Helper IDistributedCache implementations

There are two implementations of IDistributedCache built in to ASP.NET Core. One is based on SQL Server, and the other is based on Redis. Third-party implementations are also available, such as NCache. Details of these implementations can be found at Distributed caching in ASP.NET Core. Both implementations involve setting an instance of `IDistributedCache` in `Startup`.

There are no tag attributes specifically associated with using any specific implementation of `IDistributedCache`.

Environment Tag Helper in ASP.NET Core

Article • 06/03/2022

By Peter Kellner and Hisham Bin Ateya

The Environment Tag Helper conditionally renders its enclosed content based on the current hosting environment. The Environment Tag Helper's single attribute, `names`, is a comma-separated list of environment names. If any of the provided environment names match the current environment, the enclosed content is rendered.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

Environment Tag Helper Attributes

names

`names` accepts a single hosting environment name or a comma-separated list of hosting environment names that trigger the rendering of the enclosed content.

Environment values are compared to the current value returned by IWebHostEnvironment.EnvironmentName. The comparison ignores case.

The following example uses an Environment Tag Helper. The content is rendered if the hosting environment is Staging or Production:

CSHTML

```
<environment names="Staging,Production">
    <strong>IWebHostEnvironment.EnvironmentName is Staging or
Production</strong>
</environment>
```

include and exclude attributes

`include` & `exclude` attributes control rendering the enclosed content based on the included or excluded hosting environment names.

include

The `include` property exhibits similar behavior to the `names` attribute. An environment listed in the `include` attribute value must match the app's hosting environment (IWebHostEnvironment.EnvironmentName) to render the content of the `<environment>` tag.

CSHTML

```
<environment include="Staging,Production">
    <strong>IWebHostEnvironment.EnvironmentName is Staging or
Production</strong>
</environment>
```

exclude

In contrast to the `include` attribute, the content of the `<environment>` tag is rendered when the hosting environment doesn't match an environment listed in the `exclude` attribute value.

CSHTML

```
<environment exclude="Development">
    <strong>IWebHostEnvironment.EnvironmentName is not Development</strong>
</environment>
```

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Image Tag Helper in ASP.NET Core

Article • 06/03/2022

By Peter Kellner

The Image Tag Helper enhances the `<img>` tag to provide cache-busting behavior for static image files.

A cache-busting string is a unique value representing the hash of the static image file appended to the asset's URL. The unique string prompts clients (and some proxies) to reload the image from the host web server and not from the client's cache.

If the image source (`src`) is a static file on the host web server:

- A unique cache-busting string is appended as a query parameter to the image source.
- If the file on the host web server changes, a unique request URL is generated that includes the updated request parameter.

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

Image Tag Helper Attributes

src

To activate the Image Tag Helper, the `src` attribute is required on the `<img>` element.

The image source (`src`) must point to a physical static file on the server. If the `src` is a remote URI, the cache-busting query string parameter isn't generated.

asp-append-version

When `asp-append-version` is specified with a `true` value along with a `src` attribute, the Image Tag Helper is invoked.

The following example uses an Image Tag Helper:

CSHTML

```
<img src="~/images/asplogo.png" asp-append-version="true">
```

If the static file exists in the directory */wwwroot/images/*, the generated HTML is similar to the following (the hash will be different):

HTML

```
<img src="/images/asplogo.png?
v=Kl_dqr9NVtnMdsM2MUg4qthUnWZm5T1fCEimBPWDNgM">
```

The value assigned to the parameter `v` is the hash value of the `asplogo.png` file on disk. If the web server is unable to obtain read access to the static file, no `v` parameter is added to the `src` attribute in the rendered markup.

For a Tag Helper to generate a version for a static file outside `wwwroot`, see Serve files from multiple locations

Hash caching behavior

The Image Tag Helper uses the cache provider on the local web server to store the calculated `Sha512` hash of a given file. If the file is requested multiple times, the hash isn't recalculated. The cache is invalidated by a file watcher that's attached to the file when the file's `Sha512` hash is calculated. When the file changes on disk, a new hash is calculated and cached.

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Link Tag Helper in ASP.NET Core

Article • 06/27/2022

By Rick Anderson

The Link Tag Helper generates a link to a primary or fall back CSS file. Typically the primary CSS file is on a Content Delivery Network (CDN).

A CDN:

- Provides several performance advantages vs hosting the asset with the web app.
- Should not be relied on as the only source for the asset. CDNs are not always available, therefore a reliable fallback should be used. Typically the fallback is the site hosting the web app.

The Link Tag Helper allows you to specify a CDN for the CSS file and a fallback when the CDN is not available. The Link Tag Helper provides the performance advantage of a CDN with the robustness of local hosting.

The following Razor markup shows the `head` element of a layout file created with the ASP.NET Core web app template:

CSHTML

```
<!DOCTYPE html>
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>@ViewData["Title"] - WebLinkTH</title>

    <environment include="Development">
        <link rel="stylesheet" href="~/lib/bootstrap/dist/css/bootstrap.css"
/>
    </environment>
    <environment exclude="Development">
        <link rel="stylesheet"
              href="https://cdnjs.cloudflare.com/ajax/libs/twitter-
bootstrap/4.1.3/css/bootstrap.css"
              asp-fallback-href="~/lib/bootstrap/dist/css/bootstrap.css"
              asp-fallback-test-class="sr-only" asp-fallback-test-
property="position"
              asp-fallback-test-value="absolute"
              crossorigin="anonymous"
              integrity="sha256-
eSi1q2PG6J7g7ib17yAaWMcrr5GrtohYChqibrV7PBE=" />
    </environment>
```

```
    <link rel="stylesheet" href="~/css/site.css" />
</head>
```

The following is rendered HTML from the preceding code (in a non-Development environment):

HTML

```
<html>
<head>
    <meta charset="utf-8" />
    <meta name="viewport" content="width=device-width, initial-scale=1.0" />
    <title>Home page - WebLinkTH</title>
    <link rel="stylesheet"
href="https://cdnjs.cloudflare.com/ajax/libs/twitter-
bootstrap/4.1.3/css/bootstrap.css"
          crossorigin="anonymous" integrity="sha256-eS<snip>BE=" />
    <meta name="x-stylesheet-fallback-test" content="" class="sr-only" />
    <script>
        !function (a, b, c, d) {
            var e, f = document,
                g = f.getElementsByTagName("SCRIPT"),
                h = g[g.length - 1].previousElementSibling,
                i = f.defaultView && f.defaultView.getComputedStyle ?
f.defaultView.getComputedStyle(h) : h.currentStyle;
            if (i && i[a] !== b) for (e = 0; e < c.length; e++)
                f.write('<link href="' + c[e] + '" ' + d + "/>")
        }
            ("position", "absolute",
["\/lib\/bootstrap\/dist\/css\/bootstrap.css"],
                "rel=\u0022stylesheet\u0022
crossorigin=\u0022anonymous\u0022 integrity=\abc<snip>BE=\u0022 ");
    </script>

    <link rel="stylesheet" href="/css/site.css" />
</head>
```

In the preceding code, the Link Tag Helper generated the `<meta name="x-stylesheet-fallback-test" content="" class="sr-only" />` element and the following JavaScript which is used to verify the requested `bootstrap.css` file is available on the CDN. In this case, the CSS file was available so the Tag Helper generated the `<link />` element with the CDN CSS file.

Commonly used Link Tag Helper attributes

See Link Tag Helper for all the Link Tag Helper attributes, properties, and methods.

href

Preferred address of the linked resource. The address is passed thought to the generated HTML in all cases.

asp-fallback-href

The URL of a CSS stylesheet to fallback to in the case the primary URL fails.

asp-fallback-test-class

The class name defined in the stylesheet to use for the fallback test. For more information, see FallbackTestClass.

asp-fallback-test-property

The CSS property name to use for the fallback test. For more information, see FallbackTestProperty.

asp-fallback-test-value

The CSS property value to use for the fallback test. For more information, see FallbackTestValue.

Partial Tag Helper in ASP.NET Core

Article • 06/18/2024

By Scott Addie

For an overview of Tag Helpers, see Tag Helpers in ASP.NET Core.

View or download sample code (how to download)

Overview

The Partial Tag Helper is used for rendering a partial view in Razor Pages and MVC apps. Consider that it:

- Requires ASP.NET Core 2.1 or later.
- Is an alternative to HTML Helper syntax.
- Renders the partial view asynchronously.

The HTML Helper options for rendering a partial view include:

- @await Html.PartialAsync
- @await Html.RenderPartialAsync
- @Html.Partial
- @Html.RenderPartial

The *Product* model is used in samples throughout this document:

C#

```
namespace TagHelpersBuiltIn.Models
{
    public class Product
    {
        public int Number { get; set; }

        public string Name { get; set; }

        public string Description { get; set; }
    }
}
```

An inventory of the Partial Tag Helper attributes follows.

name

The `name` attribute is required. It indicates the name or the path of the partial view to be rendered. When a partial view name is provided, the view discovery process is initiated. That process is bypassed when an explicit path is provided. For all acceptable `name` values, see Partial view discovery.

The following markup uses an explicit path, indicating that `_ProductPartial.cshtml` is to be loaded from the *Shared* folder. Using the for attribute, a model is passed to the partial view for binding.

CSHTML

```
<partial name="Shared/_ProductPartial.cshtml" for="Product">
```

for

The `for` attribute assigns a ModelExpression to be evaluated against the current model. A `ModelExpression` infers the `@Model.` syntax. For example, `for="Product"` can be used instead of `for="@Model.Product"`. This default inference behavior is overridden by using the `@` symbol to define an inline expression.

The following markup loads `_ProductPartial.cshtml`:

CSHTML

```
<partial name="_ProductPartial" for="Product">
```

The partial view is bound to the associated page model's `Product` property:

C#

```
using Microsoft.AspNetCore.Mvc.RazorPages;
using TagHelpersBuiltIn.Models;

namespace TagHelpersBuiltIn.Pages
{
    public class ProductModel : PageModel
    {
        public Product Product { get; set; }

        public void OnGet()
        {
            Product = new Product
            {
                Number = 1,
                Name = "Test product",
```

```
                Description = "This is a test product"
            };
        }
    }
}
```

model

The `model` attribute assigns a model instance to pass to the partial view. The `model` attribute can't be used with the for attribute.

In the following markup, a new `Product` object is instantiated and passed to the `model` attribute for binding:

CSHTML

```
<partial name="_ProductPartial"
         model='new Product { Number = 1, Name = "Test product", Description
= "This is a test" }'>
```

view-data

The `view-data` attribute assigns a ViewDataDictionary to pass to the partial view. The following markup makes the entire ViewData collection accessible to the partial view:

CSHTML

```
@{
    ViewData["IsNumberReadOnly"] = true;
}

<partial name="_ProductViewDataPartial" for="Product" view-data="ViewData">
```

In the preceding code, the `IsNumberReadOnly` key value is set to `true` and added to the ViewData collection. Consequently, `ViewData["IsNumberReadOnly"]` is made accessible within the following partial view:

CSHTML

```
@model TagHelpersBuiltIn.Models.Product

<div class="form-group">
    <label asp-for="Number"></label>
    @if ((bool)ViewData["IsNumberReadOnly"])
```

```
    {
        <input asp-for="Number" type="number" class="form-control" readonly
/>
    }
    else
    {
        <input asp-for="Number" type="number" class="form-control" />
    }
</div>
<div class="form-group">
    <label asp-for="Name"></label>
    <input asp-for="Name" type="text" class="form-control" />
</div>
<div class="form-group">
    <label asp-for="Description"></label>
    <textarea asp-for="Description" rows="4" cols="50" class="form-control">
</textarea>
</div>
```

In this example, the value of `ViewData["IsNumberReadOnly"]` determines whether the *Number* field is displayed as read only.

Migrate from an HTML Helper

Consider the following asynchronous HTML Helper example. A collection of products is iterated and displayed. Per the `PartialAsync` method's first parameter, the `_ProductPartial.cshtml` partial view is loaded. An instance of the `Product` model is passed to the partial view for binding.

CSHTML

```
@foreach (var product in Model.Products)
{
    @await Html.PartialAsync("_ProductPartial", product)
}
```

The following Partial Tag Helper achieves the same asynchronous rendering behavior as the `PartialAsync` HTML Helper. The `model` attribute is assigned a `Product` model instance for binding to the partial view.

CSHTML

```
@foreach (var product in Model.Products)
{
    <partial name="_ProductPartial" model="@product" />
}
```

Persist Component State Tag Helper in ASP.NET Core

Article • 10/02/2023

The Persist Component State Tag Helper saves the state of non-routable Razor components rendered in a page or view of a Razor Pages or MVC app.

Prerequisites

Follow the guidance in the *Use non-routable components in pages or views* section of the Integrate ASP.NET Core Razor components into ASP.NET Core apps article.

Persist state for prerendered components

To persist state for prerendered components, use the Persist Component State Tag Helper (reference source). Add the Tag Helper's tag, `<persist-component-state />`, inside the closing `</body>` tag of the layout in an app that prerenders components.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see **How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205)**.

In `Pages/Shared/_Layout.cshtml` for embedded components that are either WebAssembly prerendered (`WebAssemblyPrerendered`) or server prerendered (`ServerPrerendered`):

CSHTML

```
<body>
    ...

    <persist-component-state />
</body>
```

Decide what state to persist using the PersistentComponentState service. PersistentComponentState.RegisterOnPersisting registers a callback to persist the component state before the app is paused. The state is retrieved when the application resumes.

For more information and examples, see Prerender ASP.NET Core Razor components.

Script Tag Helper in ASP.NET Core

Article • 09/12/2024

By Rick Anderson

The Script Tag Helper generates a link to a primary or fall back script file. Typically the primary script file is on a Content Delivery Network (CDN).

A CDN:

- Provides several performance advantages vs hosting the asset with the web app.
- Should not be relied on as the only source for the asset. CDNs are not always available, therefore a reliable fallback should be used. Typically the fallback is the site hosting the web app.

The Script Tag Helper allows you to specify a CDN for the script file and a fallback when the CDN is not available. The Script Tag Helper provides the performance advantage of a CDN with the robustness of local hosting.

The following Razor markup shows a `script` element with a fallback:

HTML

```
<script src="https://ajax.aspnetcdn.com/ajax/jquery/jquery-3.3.1.js"
        asp-fallback-src="~/lib/jquery/dist/jquery.js"
        asp-fallback-test="window.jQuery"
        crossorigin="anonymous"
        integrity="sha384-
tsQFqpEReu7ZLhBV2VZlAu7zcOV+rXbYlF2cqB8txI/8aZajjp4Bqd+V6D5IgvKT">
</script>
```

Don't use the `<script>` element's defer attribute to defer loading the CDN script. The Script Tag Helper renders JavaScript that immediately executes the asp-fallback-test expression. The expression fails if loading the CDN script is deferred.

Commonly used Script Tag Helper attributes

See Script Tag Helper for all the Script Tag Helper attributes, properties, and methods.

src

Address of the external script to use.

asp-append-version

When `asp-append-version` is specified with a `true` value along with a src attribute, a unique version is generated.

For a Tag Helper to generate a version for a static file outside `wwwroot`, see Serve files from multiple locations

asp-fallback-src

The URL of a Script tag to fallback to in the case the primary one fails.

asp-fallback-src-exclude

A comma-separated list of globbed file patterns of JavaScript scripts to exclude from the fallback list, in the case the primary one fails. The glob patterns are assessed relative to the application's `webroot` setting. Must be used in conjunction with `asp-fallback-src-include`.

asp-fallback-src-include

A comma-separated list of globbed file patterns of JavaScript scripts to fallback to in the case the primary one fails. The glob patterns are assessed relative to the application's `webroot` setting.

asp-fallback-test

The script method defined in the primary script to use for the fallback test. For more information, see FallbackTestExpression.

asp-order

When a set of `ITagHelper` instances are executed, their `Init(TagHelperContext)` methods are first invoked in the specified order; then their `ProcessAsync(TagHelperContext, TagHelperOutput)` methods are invoked in the specified order. Lower values are executed first.

asp-src-exclude

A comma-separated list of globbed file patterns of JavaScript scripts to exclude from loading. The glob patterns are assessed relative to the application's `webroot` setting. Must be used in conjunction with `asp-src-include`.

asp-src-include

A comma-separated list of globbed file patterns of JavaScript scripts to load. The glob patterns are assessed relative to the application's `webroot` setting.

asp-suppress-fallback-integrity

Boolean value that determines if an integrity hash will be compared with the asp-fallback-src value.

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Tag Helpers in forms in ASP.NET Core

Article • 09/27/2024

By Rick Anderson, N. Taylor Mullen, Dave Paquette, and Jerrie Pelser

This document demonstrates working with Forms and the HTML elements commonly used on a Form. The HTML Form element provides the primary mechanism web apps use to post back data to the server. Most of this document describes Tag Helpers and how they can help you productively create robust HTML forms. We recommend you read Introduction to Tag Helpers before you read this document.

In many cases, HTML Helpers provide an alternative approach to a specific Tag Helper, but it's important to recognize that Tag Helpers don't replace HTML Helpers and there's not a Tag Helper for each HTML Helper. When an HTML Helper alternative exists, it's mentioned.

The Form Tag Helper

The Form Tag Helper:

- Generates the HTML <FORM> `action` attribute value for a MVC controller action or named route
- Generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method)
- Provides the `asp-route-<Parameter Name>` attribute, where `<Parameter Name>` is added to the route values. The `routeValues` parameters to `Html.BeginForm` and `Html.BeginRouteForm` provide similar functionality.
- Has an HTML Helper alternative `Html.BeginForm` and `Html.BeginRouteForm`

Sample:

CSHTML

```
<form asp-controller="Demo" asp-action="Register" method="post">
    <!-- Input and Submit elements -->
</form>
```

The Form Tag Helper above generates the following HTML:

HTML

```
<form method="post" action="/Demo/Register">
    <!-- Input and Submit elements -->
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The MVC runtime generates the `action` attribute value from the Form Tag Helper attributes `asp-controller` and `asp-action`. The Form Tag Helper also generates a hidden Request Verification Token to prevent cross-site request forgery (when used with the `[ValidateAntiForgeryToken]` attribute in the HTTP Post action method). Protecting a pure HTML Form from cross-site request forgery is difficult, the Form Tag Helper provides this service for you.

Using a named route

The `asp-route` Tag Helper attribute can also generate markup for the HTML `action` attribute. An app with a route named `register` could use the following markup for the registration page:

CSHTML

```
<form asp-route="register" method="post">
    <!-- Input and Submit elements -->
</form>
```

Many of the views in the *Views/Account* folder (generated when you create a new web app with *Individual User Accounts*) contain the asp-route-returnurl attribute:

CSHTML

```
<form asp-controller="Account" asp-action="Login"
     asp-route-returnurl="@ViewData["ReturnUrl"]"
     method="post" class="form-horizontal" role="form">
```

> **Note**
>
> With the built in templates, `returnUrl` is only populated automatically when you try to access an authorized resource but are not authenticated or authorized. When you attempt an unauthorized access, the security middleware redirects you to the login page with the `returnUrl` set.

The Form Action Tag Helper

The Form Action Tag Helper generates the `formaction` attribute on the generated `<button ...>` or `<input type="image" ...>` tag. The `formaction` attribute controls where a form submits its data. It binds to <input> elements of type `image` and <button> elements. The Form Action Tag Helper enables the usage of several AnchorTagHelper `asp-` attributes to control what `formaction` link is generated for the corresponding element.

Supported AnchorTagHelper attributes to control the value of `formaction`:

Expand table

Attribute	Description
asp-controller	The name of the controller.
asp-action	The name of the action method.
asp-area	The name of the area.
asp-page	The name of the Razor page.
asp-page-handler	The name of the Razor page handler.
asp-route	The name of the route.
asp-route-{value}	A single URL route value. For example, `asp-route-id="1234"`.
asp-all-route-data	All route values.
asp-fragment	The URL fragment.

Submit to controller example

The following markup submits the form to the `Index` action of `HomeController` when the input or button are selected:

CSHTML

```
<form method="post">
    <button asp-controller="Home" asp-action="Index">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-controller="Home"
                                asp-action="Index">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home">
</form>
```

Submit to page example

The following markup submits the form to the `About` Razor Page:

CSHTML

```
<form method="post">
    <button asp-page="About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-page="About">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/About">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/About">
</form>
```

Submit to route example

Consider the `/Home/Test` endpoint:

C#

```
public class HomeController : Controller
{
    [Route("/Home/Test", Name = "Custom")]
    public string Test()
    {
        return "This is the test page";
    }
}
```

The following markup submits the form to the `/Home/Test` endpoint.

CSHTML

```
<form method="post">
    <button asp-route="Custom">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" asp-route="Custom">
</form>
```

The previous markup generates following HTML:

HTML

```
<form method="post">
    <button formaction="/Home/Test">Click Me</button>
    <input type="image" src="..." alt="Or Click Me" formaction="/Home/Test">
</form>
```

The Input Tag Helper

The Input Tag Helper binds an HTML <input> element to a model expression in your razor view.

Syntax:

CSHTML

```
<input asp-for="<Expression Name>">
```

The Input Tag Helper:

- Generates the `id` and `name` HTML attributes for the expression name specified in the `asp-for` attribute. `asp-for="Property1.Property2"` is equivalent to `m => m.Property1.Property2`. The name of the expression is what is used for the `asp-for` attribute value. See the Expression names section for additional information.
- Sets the HTML `type` attribute value based on the model type and data annotation attributes applied to the model property
- Won't overwrite the HTML `type` attribute value when one is specified
- Generates HTML5 validation attributes from data annotation attributes applied to model properties
- Has an HTML Helper feature overlap with `Html.TextBoxFor` and `Html.EditorFor`. See the HTML Helper alternatives to Input Tag Helper section for details.

- Provides strong typing. If the name of the property changes and you don't update the Tag Helper you'll get an error similar to the following:

```
An error occurred during the compilation of a resource required to
process
this request. Please review the following specific error details and
modify
your source code appropriately.

Type expected
'RegisterViewModel' does not contain a definition for 'Email' and no
extension method 'Email' accepting a first argument of type
'RegisterViewModel'
could be found (are you missing a using directive or an assembly
reference?)
```

The `Input` Tag Helper sets the HTML `type` attribute based on the .NET type. The following table lists some common .NET types and generated HTML type (not every .NET type is listed).

Expand table

.NET type	Input Type
Bool	type="checkbox"
String	type="text"
DateTime	type="datetime-local"
Byte	type="number"
Int	type="number"
Single, Double	type="number"

The following table shows some common data annotations attributes that the input tag helper will map to specific input types (not every validation attribute is listed):

Expand table

Attribute	Input Type
[EmailAddress]	type="email"
[Url]	type="url"

Attribute	Input Type
[HiddenInput]	type="hidden"
[Phone]	type="tel"
[DataType(DataType.Password)]	type="password"
[DataType(DataType.Date)]	type="date"
[DataType(DataType.Time)]	type="time"

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterInput" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <button type="submit">Register</button>
</form>
```

The code above generates the following HTML:

HTML

```
<form method="post" action="/Demo/RegisterInput">
    Email:
    <input type="email" data-val="true"
```

```
            data-val-email="The Email Address field is not a valid email
address."
            data-val-required="The Email Address field is required."
            id="Email" name="Email" value=""><br>
    Password:
    <input type="password" data-val="true"
            data-val-required="The Password field is required."
            id="Password" name="Password"><br>
    <button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

The data annotations applied to the `Email` and `Password` properties generate metadata on the model. The Input Tag Helper consumes the model metadata and produces HTML5 `data-val-*` attributes (see Model Validation). These attributes describe the validators to attach to the input fields. This provides unobtrusive HTML5 and jQuery validation. The unobtrusive attributes have the format `data-val-rule="Error Message"`, where rule is the name of the validation rule (such as `data-val-required`, `data-val-email`, `data-val-maxlength`, etc.) If an error message is provided in the attribute, it's displayed as the value for the `data-val-rule` attribute. There are also attributes of the form `data-val-ruleName-argumentName="argumentValue"` that provide additional details about the rule, for example, `data-val-maxlength-max="1024"` .

When binding multiple `input` controls to the same property, the generated controls share the same `id`, which makes the generated mark-up invalid. To prevent duplicates, specify the `id` attribute for each control explicitly.

Checkbox hidden input rendering

Checkboxes in HTML5 don't submit a value when they're unchecked. To enable a default value to be sent for an unchecked checkbox, the Input Tag Helper generates an additional hidden input for checkboxes.

For example, consider the following Razor markup that uses the Input Tag Helper for a boolean model property `IsChecked`:

CSHTML

```
<form method="post">
    <input asp-for="@Model.IsChecked" />
    <button type="submit">Submit</button>
</form>
```

The preceding Razor markup generates HTML markup similar to the following:

HTML

```
<form method="post">
    <input name="IsChecked" type="checkbox" value="true" />
    <button type="submit">Submit</button>

    <input name="IsChecked" type="hidden" value="false" />
</form>
```

The preceding HTML markup shows an additional hidden input with a name of `IsChecked` and a value of `false`. By default, this hidden input is rendered at the end of the form. When the form is submitted:

- If the `IsChecked` checkbox input is checked, both `true` and `false` are submitted as values.
- If the `IsChecked` checkbox input is unchecked, only the hidden input value `false` is submitted.

The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

To configure the behavior of the hidden input rendering, set the CheckBoxHiddenInputRenderMode property on MvcViewOptions.HtmlHelperOptions. For example:

C#

```
services.Configure<MvcViewOptions>(options =>
    options.HtmlHelperOptions.CheckBoxHiddenInputRenderMode =
        CheckBoxHiddenInputRenderMode.None);
```

The preceding code disables hidden input rendering for checkboxes by setting `CheckBoxHiddenInputRenderMode` to CheckBoxHiddenInputRenderMode.None. For all available rendering modes, see the CheckBoxHiddenInputRenderMode enum.

HTML Helper alternatives to Input Tag Helper

`Html.TextBox`, `Html.TextBoxFor`, `Html.Editor` and `Html.EditorFor` have overlapping features with the Input Tag Helper. The Input Tag Helper will automatically set the `type` attribute; `Html.TextBox` and `Html.TextBoxFor` won't. `Html.Editor` and `Html.EditorFor` handle collections, complex objects and templates; the Input Tag Helper doesn't. The

Input Tag Helper, `Html.EditorFor` and `Html.TextBoxFor` are strongly typed (they use lambda expressions); `Html.TextBox` and `Html.Editor` are not (they use expression names).

HtmlAttributes

`@Html.Editor()` and `@Html.EditorFor()` use a special `ViewDataDictionary` entry named `htmlAttributes` when executing their default templates. This behavior is optionally augmented using `additionalViewData` parameters. The key "htmlAttributes" is case-insensitive. The key "htmlAttributes" is handled similarly to the `htmlAttributes` object passed to input helpers like `@Html.TextBox()`.

CSHTML

```
@Html.EditorFor(model => model.YourProperty,
  new { htmlAttributes = new { @class="myCssClass", style="Width:100px" } })
```

Expression names

The `asp-for` attribute value is a `ModelExpression` and the right hand side of a lambda expression. Therefore, `asp-for="Property1"` becomes `m => m.Property1` in the generated code which is why you don't need to prefix with `Model`. You can use the "@" character to start an inline expression and move before the `m.`:

CSHTML

```
@{
  var joe = "Joe";
}

<input asp-for="@joe">
```

Generates the following:

HTML

```
<input type="text" id="joe" name="joe" value="Joe">
```

With collection properties, `asp-for="CollectionProperty[23].Member"` generates the same name as `asp-for="CollectionProperty[i].Member"` when `i` has the value `23`.

When ASP.NET Core MVC calculates the value of `ModelExpression`, it inspects several sources, including `ModelState`. Consider `<input type="text" asp-for="Name">`. The calculated `value` attribute is the first non-null value from:

- `ModelState` entry with key "Name".
- Result of the expression `Model.Name`.

Navigating child properties

You can also navigate to child properties using the property path of the view model. Consider a more complex model class that contains a child `Address` property.

C#

```
public class AddressViewModel
{
    public string AddressLine1 { get; set; }
}
```

C#

```
public class RegisterAddressViewModel
{
    public string Email { get; set; }

    [DataType(DataType.Password)]
    public string Password { get; set; }

    public AddressViewModel Address { get; set; }
}
```

In the view, we bind to `Address.AddressLine1`:

CSHTML

```
@model RegisterAddressViewModel

<form asp-controller="Demo" asp-action="RegisterAddress" method="post">
    <label>Email: <input asp-for="Email" /></label> <br />
    <label>Password: <input asp-for="Password" /></label><br />
    <label>Address: <input asp-for="Address.AddressLine1" /></label><br />
    <button type="submit">Register</button>
</form>
```

The following HTML is generated for `Address.AddressLine1`:

HTML

```
<input type="text" id="Address_AddressLine1" name="Address.AddressLine1"
value="">
```

Expression names and Collections

Sample, a model containing an array of `Colors`:

C#

```
public class Person
{
    public List<string> Colors { get; set; }

    public int Age { get; set; }
}
```

The action method:

C#

```
public IActionResult Edit(int id, int colorIndex)
{
    ViewData["Index"] = colorIndex;
    return View(GetPerson(id));
}
```

The following Razor shows how you access a specific `Color` element:

CSHTML

```
@model Person
@{
    var index = (int)ViewData["index"];
}

<form asp-controller="ToDo" asp-action="Edit" method="post">
    @Html.EditorFor(m => m.Colors[index])
    <label asp-for="Age"></label>
    <input asp-for="Age" /><br />
    <button type="submit">Post</button>
</form>
```

The `Views/Shared/EditorTemplates/String.cshtml` template:

CSHTML

```
@model string

<label asp-for="@Model"></label>
<input asp-for="@Model" /> <br />
```

Sample using `List<T>`:

C#

```
public class ToDoItem
{
    public string Name { get; set; }

    public bool IsDone { get; set; }
}
```

The following Razor shows how to iterate over a collection:

CSHTML

```
@model List<ToDoItem>

<form asp-controller="ToDo" asp-action="Edit" method="post">
    <table>
        <tr> <th>Name</th> <th>Is Done</th> </tr>

        @for (int i = 0; i < Model.Count; i++)
        {
            <tr>
                @Html.EditorFor(model => model[i])
            </tr>
        }

    </table>
    <button type="submit">Save</button>
</form>
```

The `Views/Shared/EditorTemplates/ToDoItem.cshtml` template:

CSHTML

```
@model ToDoItem

<td>
    <label asp-for="@Model.Name"></label>
    @Html.DisplayFor(model => model.Name)
</td>
<td>
    <input asp-for="@Model.IsDone" />
```

```
</td>

@*
    This template replaces the following Razor which evaluates the indexer
three times.
    <td>
         <label asp-for="@Model[i].Name"></label>
         @Html.DisplayFor(model => model[i].Name)
     </td>
     <td>
         <input asp-for="@Model[i].IsDone" />
     </td>
*@
```

`foreach` should be used if possible when the value is going to be used in an `asp-for` or `Html.DisplayFor` equivalent context. In general, `for` is better than `foreach` (if the scenario allows it) because it doesn't need to allocate an enumerator; however, evaluating an indexer in a LINQ expression can be expensive and should be minimized.

> ⓘ **Note**
>
> The commented sample code above shows how you would replace the lambda expression with the `@` operator to access each `ToDoItem` in the list.

The Textarea Tag Helper

The `Textarea Tag Helper` tag helper is similar to the Input Tag Helper.

- Generates the `id` and `name` attributes, and the data validation attributes from the model for a <textarea> element.
- Provides strong typing.
- HTML Helper alternative: `Html.TextAreaFor`

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class DescriptionViewModel
```

```
    {
        [MinLength(5)]
        [MaxLength(1024)]
        public string Description { get; set; }
    }
}
```

CSHTML

```
@model DescriptionViewModel

<form asp-controller="Demo" asp-action="RegisterTextArea" method="post">
    <textarea asp-for="Description"></textarea>
    <button type="submit">Test</button>
</form>
```

The following HTML is generated:

HTML

```
<form method="post" action="/Demo/RegisterTextArea">
  <textarea data-val="true"
   data-val-maxlength="The field Description must be a string or array type
with a maximum length of &#x27;1024&#x27;."
   data-val-maxlength-max="1024"
   data-val-minlength="The field Description must be a string or array type
with a minimum length of &#x27;5&#x27;."
   data-val-minlength-min="5"
   id="Description" name="Description">
  </textarea>
  <button type="submit">Test</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Label Tag Helper

- Generates the label caption and `for` attribute on a <label> element for an expression name
- HTML Helper alternative: `Html.LabelFor`.

The `Label Tag Helper` provides the following benefits over a pure HTML label element:

- You automatically get the descriptive label value from the `Display` attribute. The intended display name might change over time, and the combination of `Display` attribute and Label Tag Helper will apply the `Display` everywhere it's used.

- Less markup in source code
- Strong typing with the model property.

Sample:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class SimpleViewModel
    {
        [Required]
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }
    }
}
```

CSHTML

```
@model SimpleViewModel

<form asp-controller="Demo" asp-action="RegisterLabel" method="post">
    <label asp-for="Email"></label>
    <input asp-for="Email" /> <br />
</form>
```

The following HTML is generated for the `<label>` element:

HTML

```
<label for="Email">Email Address</label>
```

The Label Tag Helper generated the `for` attribute value of "Email", which is the ID associated with the `<input>` element. The Tag Helpers generate consistent `id` and `for` elements so they can be correctly associated. The caption in this sample comes from the `Display` attribute. If the model didn't contain a `Display` attribute, the caption would be the property name of the expression. To override the default caption, add a caption inside the label tag.

The Validation Tag Helpers

There are two Validation Tag Helpers. The `Validation Message Tag Helper` (which displays a validation message for a single property on your model), and the `Validation Summary Tag Helper` (which displays a summary of validation errors). The `Input Tag Helper` adds HTML5 client side validation attributes to input elements based on data annotation attributes on your model classes. Validation is also performed on the server. The Validation Tag Helper displays these error messages when a validation error occurs.

The Validation Message Tag Helper

- Adds the HTML5 `data-valmsg-for="property"` attribute to the span element, which attaches the validation error messages on the input field of the specified model property. When a client side validation error occurs, jQuery displays the error message in the `<span>` element.
- Validation also takes place on the server. Clients may have JavaScript disabled and some validation can only be done on the server side.
- HTML Helper alternative: `Html.ValidationMessageFor`

The `Validation Message Tag Helper` is used with the `asp-validation-for` attribute on an HTML span element.

CSHTML

```
<span asp-validation-for="Email"></span>
```

The Validation Message Tag Helper will generate the following HTML:

HTML

```
<span class="field-validation-valid"
  data-valmsg-for="Email"
  data-valmsg-replace="true"></span>
```

You generally use the `Validation Message Tag Helper` after an `Input` Tag Helper for the same property. Doing so displays any validation error messages near the input that caused the error.

> ⓘ **Note**
>
> You must have a view with the correct JavaScript and jQuery script references in place for client side validation. See Model Validation for more information.

When a server side validation error occurs (for example when you have custom server side validation or client-side validation is disabled), MVC places that error message as the body of the `<span>` element.

HTML

```
<span class="field-validation-error" data-valmsg-for="Email"
            data-valmsg-replace="true">
   The Email Address field is required.
</span>
```

The Validation Summary Tag Helper

- Targets `<div>` elements with the `asp-validation-summary` attribute
- HTML Helper alternative: `@Html.ValidationSummary`

The `Validation Summary Tag Helper` is used to display a summary of validation messages. The `asp-validation-summary` attribute value can be any of the following:

Expand table

asp-validation-summary	Validation messages displayed
`All`	Property and model level
`ModelOnly`	Model
`None`	None

Sample

In the following example, the data model has `DataAnnotation` attributes, which generates validation error messages on the `<input>` element. When a validation error occurs, the Validation Tag Helper displays the error message:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public class RegisterViewModel
    {
        [Required]
```

```
        [EmailAddress]
        [Display(Name = "Email Address")]
        public string Email { get; set; }

        [Required]
        [DataType(DataType.Password)]
        public string Password { get; set; }
    }
}
```

CSHTML

```
@model RegisterViewModel

<form asp-controller="Demo" asp-action="RegisterValidation" method="post">
    <div asp-validation-summary="ModelOnly"></div>
    <label>Email: <input asp-for="Email" /></label> <br />
    <span asp-validation-for="Email"></span><br />
    <label>Password: <input asp-for="Password" /></label><br />
    <span asp-validation-for="Password"></span><br />
    <button type="submit">Register</button>
</form>
```

The generated HTML (when the model is valid):

HTML

```
<form action="/DemoReg/Register" method="post">
  <label>Email: <input name="Email" id="Email" type="email" value=""
   data-val-required="The Email field is required."
   data-val-email="The Email field is not a valid email address."
   data-val="true"></label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Email"></span><br>
  <label>Password: <input name="Password" id="Password" type="password"
   data-val-required="The Password field is required." data-val="true">
</label><br>
  <span class="field-validation-valid" data-valmsg-replace="true"
   data-valmsg-for="Password"></span><br>
  <button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

The Select Tag Helper

- Generates select and associated option elements for properties of your model.
- Has an HTML Helper alternative `Html.DropDownListFor` and `Html.ListBoxFor`

The `Select Tag Helper` `asp-for` specifies the model property name for the select element and `asp-items` specifies the option elements. For example:

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Sample:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModel
    {
        public string Country { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA" },
        };
    }
}
```

The `Index` method initializes the `CountryViewModel`, sets the selected country and passes it to the `Index` view.

C#

```
public IActionResult Index()
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

The HTTP POST `Index` method displays the selection:

C#

```
[HttpPost]
[ValidateAntiForgeryToken]
```

```
public IActionResult Index(CountryViewModel model)
{
    if (ModelState.IsValid)
    {
        var msg = model.Country + " selected";
        return RedirectToAction("IndexSuccess", new { message = msg });
    }

    // If we got this far, something failed; redisplay form.
    return View(model);
}
```

The `Index` view:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="Index" method="post">
    <select asp-for="Country" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Which generates the following HTML (with "CA" selected):

HTML

```
<form method="post" action="/">
     <select id="Country" name="Country">
       <option value="MX">Mexico</option>
       <option selected="selected" value="CA">Canada</option>
       <option value="US">USA</option>
     </select>
       <br /><button type="submit">Register</button>
     <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
   </form>
```

> **Note**
>
> We don't recommend using `ViewBag` or `ViewData` with the Select Tag Helper. A view model is more robust at providing MVC metadata and generally less problematic.

The `asp-for` attribute value is a special case and doesn't require a `Model` prefix, the other Tag Helper attributes do (such as `asp-items`)

CSHTML

```
<select asp-for="Country" asp-items="Model.Countries"></select>
```

Enum binding

It's often convenient to use `<select>` with an `enum` property and generate the `SelectListItem` elements from the `enum` values.

Sample:

C#

```
public class CountryEnumViewModel
{
    public CountryEnum EnumCountry { get; set; }
}
```

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The `GetEnumSelectList` method generates a `SelectList` object for an enum.

CSHTML

```
@model CountryEnumViewModel

<form asp-controller="Home" asp-action="IndexEnum" method="post">
    <select asp-for="EnumCountry"
            asp-items="Html.GetEnumSelectList<CountryEnum>()">
    </select>
```

```
    <br /><button type="submit">Register</button>
</form>
```

You can mark your enumerator list with the `Display` attribute to get a richer UI:

C#

```
using System.ComponentModel.DataAnnotations;

namespace FormsTagHelper.ViewModels
{
    public enum CountryEnum
    {
        [Display(Name = "United Mexican States")]
        Mexico,
        [Display(Name = "United States of America")]
        USA,
        Canada,
        France,
        Germany,
        Spain
    }
}
```

The following HTML is generated:

HTML

```
<form method="post" action="/Home/IndexEnum">
    <select data-val="true" data-val-required="The EnumCountry field is
required."
            id="EnumCountry" name="EnumCountry">
        <option value="0">United Mexican States</option>
        <option value="1">United States of America</option>
        <option value="2">Canada</option>
        <option value="3">France</option>
        <option value="4">Germany</option>
        <option selected="selected" value="5">Spain</option>
    </select>
    <br /><button type="submit">Register</button>
    <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
</form>
```

Option Group

The HTML <optgroup> element is generated when the view model contains one or more `SelectListGroup` objects.

The `CountryViewModelGroup` groups the `SelectListItem` elements into the "North America" and "Europe" groups:

C#

```
public class CountryViewModelGroup
{
    public CountryViewModelGroup()
    {
        var NorthAmericaGroup = new SelectListGroup { Name = "North America"
};
        var EuropeGroup = new SelectListGroup { Name = "Europe" };

        Countries = new List<SelectListItem>
        {
            new SelectListItem
            {
                Value = "MEX",
                Text = "Mexico",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "CAN",
                Text = "Canada",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "US",
                Text = "USA",
                Group = NorthAmericaGroup
            },
            new SelectListItem
            {
                Value = "FR",
                Text = "France",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "ES",
                Text = "Spain",
                Group = EuropeGroup
            },
            new SelectListItem
            {
                Value = "DE",
                Text = "Germany",
                Group = EuropeGroup
            }
      };
    }
```

```
    public string Country { get; set; }

    public List<SelectListItem> Countries { get; }
```

The two groups are shown below:

The generated HTML:

HTML

```
 <form method="post" action="/Home/IndexGroup">
      <select id="Country" name="Country">
          <optgroup label="North America">
              <option value="MEX">Mexico</option>
              <option value="CAN">Canada</option>
              <option value="US">USA</option>
          </optgroup>
          <optgroup label="Europe">
              <option value="FR">France</option>
              <option value="ES">Spain</option>
              <option value="DE">Germany</option>
          </optgroup>
      </select>
      <br /><button type="submit">Register</button>
      <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
  </form>
```

Multiple select

The Select Tag Helper will automatically generate the multiple = "multiple" attribute if the property specified in the `asp-for` attribute is an `IEnumerable`. For example, given the following model:

C#

```
using Microsoft.AspNetCore.Mvc.Rendering;
using System.Collections.Generic;

namespace FormsTagHelper.ViewModels
{
    public class CountryViewModelIEnumerable
    {
        public IEnumerable<string> CountryCodes { get; set; }

        public List<SelectListItem> Countries { get; } = new
List<SelectListItem>
        {
            new SelectListItem { Value = "MX", Text = "Mexico" },
            new SelectListItem { Value = "CA", Text = "Canada" },
            new SelectListItem { Value = "US", Text = "USA"    },
            new SelectListItem { Value = "FR", Text = "France" },
            new SelectListItem { Value = "ES", Text = "Spain"  },
            new SelectListItem { Value = "DE", Text = "Germany"}
         };
    }
}
```

With the following view:

CSHTML

```
@model CountryViewModelIEnumerable

<form asp-controller="Home" asp-action="IndexMultiSelect" method="post">
    <select asp-for="CountryCodes" asp-items="Model.Countries"></select>
    <br /><button type="submit">Register</button>
</form>
```

Generates the following HTML:

HTML

```
<form method="post" action="/Home/IndexMultiSelect">
    <select id="CountryCodes"
    multiple="multiple"
    name="CountryCodes"><option value="MX">Mexico</option>
<option value="CA">Canada</option>
<option value="US">USA</option>
<option value="FR">France</option>
```

```
<option value="ES">Spain</option>
<option value="DE">Germany</option>
</select>
    <br /><button type="submit">Register</button>
  <input name="__RequestVerificationToken" type="hidden" value="<removed for
brevity>">
</form>
```

No selection

If you find yourself using the "not specified" option in multiple pages, you can create a template to eliminate repeating the HTML:

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    @Html.EditorForModel()
    <br /><button type="submit">Register</button>
</form>
```

The `Views/Shared/EditorTemplates/CountryViewModel.cshtml` template:

CSHTML

```
@model CountryViewModel

<select asp-for="Country" asp-items="Model.Countries">
    <option value="">--none--</option>
</select>
```

Adding HTML <option> elements isn't limited to the *No selection* case. For example, the following view and action method will generate HTML similar to the code above:

C#

```
public IActionResult IndexNone()
{
    var model = new CountryViewModel();
    model.Countries.Insert(0, new SelectListItem("<none>", ""));
    return View(model);
}
```

CSHTML

```
@model CountryViewModel

<form asp-controller="Home" asp-action="IndexEmpty" method="post">
    <select asp-for="Country">
        <option value="">&lt;none&gt;</option>
        <option value="MX">Mexico</option>
        <option value="CA">Canada</option>
        <option value="US">USA</option>
    </select>
    <br /><button type="submit">Register</button>
</form>
```

The correct `<option>` element will be selected (contain the `selected="selected"` attribute) depending on the current `Country` value.

C#

```
public IActionResult IndexOption(int id)
{
    var model = new CountryViewModel();
    model.Country = "CA";
    return View(model);
}
```

HTML

```
 <form method="post" action="/Home/IndexEmpty">
      <select id="Country" name="Country">
          <option value="">&lt;none&gt;</option>
          <option value="MX">Mexico</option>
          <option value="CA" selected="selected">Canada</option>
          <option value="US">USA</option>
      </select>
      <br /><button type="submit">Register</button>
   <input name="__RequestVerificationToken" type="hidden" value="<removed
for brevity>">
 </form>
```

Share controllers, views, Razor Pages and more with Application Parts

Article • 06/03/2022

By Rick Anderson

View or download sample code (how to download)

An *Application Part* is an abstraction over the resources of an app. Application Parts allow ASP.NET Core to discover controllers, view components, tag helpers, Razor Pages, razor compilation sources, and more. AssemblyPart is an Application part. `AssemblyPart` encapsulates an assembly reference and exposes types and compilation references.

Feature providers work with application parts to populate the features of an ASP.NET Core app. The main use case for application parts is to configure an app to discover (or avoid loading) ASP.NET Core features from an assembly. For example, you might want to share common functionality between multiple apps. Using Application Parts, you can share an assembly (DLL) containing controllers, views, Razor Pages, razor compilation sources, Tag Helpers, and more with multiple apps. Sharing an assembly is preferred to duplicating code in multiple projects.

ASP.NET Core apps load features from ApplicationPart. The AssemblyPart class represents an application part that's backed by an assembly.

Load ASP.NET Core features

Use the Microsoft.AspNetCore.Mvc.ApplicationParts and AssemblyPart classes to discover and load ASP.NET Core features (controllers, view components, etc.). The ApplicationPartManager tracks the application parts and feature providers available. `ApplicationPartManager` is configured in `Startup.ConfigureServices`:

C#

```
// Requires using System.Reflection;
public void ConfigureServices(IServiceCollection services)
{
    var assembly = typeof(MySharedController).Assembly;
    services.AddControllersWithViews()
        .AddApplicationPart(assembly)
        .AddRazorRuntimeCompilation();

    services.Configure<MvcRazorRuntimeCompilationOptions>(options =>
```

```
    { options.FileProviders.Add(new EmbeddedFileProvider(assembly)); });
}
```

The following code provides an alternative approach to configuring `ApplicationPartManager` using `AssemblyPart`:

C#

```
// Requires using System.Reflection;
// Requires using Microsoft.AspNetCore.Mvc.ApplicationParts;
public void ConfigureServices(IServiceCollection services)
{
    var assembly = typeof(MySharedController).Assembly;
    // This creates an AssemblyPart, but does not create any related parts
for items such as views.
    var part = new AssemblyPart(assembly);
    services.AddControllersWithViews()
        .ConfigureApplicationPartManager(apm =>
apm.ApplicationParts.Add(part));
}
```

The preceding two code samples load the `SharedController` from an assembly. The `SharedController` is not in the app's project. See the WebAppParts solution sample download.

Include views

Use a Razor class library to include views in the assembly.

Prevent loading resources

Application parts can be used to *avoid* loading resources in a particular assembly or location. Add or remove members of the Microsoft.AspNetCore.Mvc.ApplicationParts collection to hide or make available resources. The order of the entries in the `ApplicationParts` collection isn't important. Configure the `ApplicationPartManager` before using it to configure services in the container. For example, configure the `ApplicationPartManager` before invoking `AddControllersAsServices`. Call `Remove` on the `ApplicationParts` collection to remove a resource.

The `ApplicationPartManager` includes parts for:

- The app's assembly and dependent assemblies.
- `Microsoft.AspNetCore.Mvc.ApplicationParts.CompiledRazorAssemblyPart`
- `Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation`

- `Microsoft.AspNetCore.Mvc.TagHelpers`.
- `Microsoft.AspNetCore.Mvc.Razor`.

Feature providers

Application feature providers examine application parts and provide features for those parts. There are built-in feature providers for the following ASP.NET Core features:

- ControllerFeatureProvider
- TagHelperFeatureProvider
- MetadataReferenceFeatureProvider
- ViewsFeatureProvider
- `internal class` RazorCompiledItemFeatureProvider

Feature providers inherit from IApplicationFeatureProvider<TFeature>, where `T` is the type of the feature. Feature providers can be implemented for any of the previously listed feature types. The order of feature providers in the `ApplicationPartManager.FeatureProviders` can impact run time behavior. Later added providers can react to actions taken by earlier added providers.

Display available features

The features available to an app can be enumerated by requesting an `ApplicationPartManager` through dependency injection:

C#

```
using AppPartsSample.ViewModels;
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.ApplicationParts;
using Microsoft.AspNetCore.Mvc.Controllers;
using System.Linq;
using Microsoft.AspNetCore.Mvc.Razor.Compilation;
using Microsoft.AspNetCore.Mvc.Razor.TagHelpers;
using Microsoft.AspNetCore.Mvc.ViewComponents;

namespace AppPartsSample.Controllers
{
    public class FeaturesController : Controller
    {
        private readonly ApplicationPartManager _partManager;

        public FeaturesController(ApplicationPartManager partManager)
        {
            _partManager = partManager;
        }
```

```
        public IActionResult Index()
        {
            var viewModel = new FeaturesViewModel();

            var controllerFeature = new ControllerFeature();
            _partManager.PopulateFeature(controllerFeature);
            viewModel.Controllers = controllerFeature.Controllers.ToList();

            var tagHelperFeature = new TagHelperFeature();
            _partManager.PopulateFeature(tagHelperFeature);
            viewModel.TagHelpers = tagHelperFeature.TagHelpers.ToList();

            var viewComponentFeature = new ViewComponentFeature();
            _partManager.PopulateFeature(viewComponentFeature);
            viewModel.ViewComponents =
viewComponentFeature.ViewComponents.ToList();

            return View(viewModel);
        }
    }
}
```

The download sample uses the preceding code to display the app features:

text

```
Controllers:
    - FeaturesController
    - HomeController
    - HelloController
    - GenericController`1
    - GenericController`1
Tag Helpers:
    - PrerenderTagHelper
    - AnchorTagHelper
    - CacheTagHelper
    - DistributedCacheTagHelper
    - EnvironmentTagHelper
    - Additional Tag Helpers omitted for brevity.
View Components:
    - SampleViewComponent
```

Discovery in application parts

HTTP 404 errors are not uncommon when developing with application parts. These errors are typically caused by missing an essential requirement for how applications parts are discovered. If your app returns an HTTP 404 error, verify the following requirements have been met:

- The `applicationName` setting needs to be set to the root assembly used for discovery. The root assembly used for discovery is normally the entry point assembly.
- The root assembly needs to have a reference to the parts used for discovery. The reference can be direct or transitive.
- The root assembly needs to reference the Web SDK. The framework has logic that stamps attributes into the root assembly that are used for discovery.

Work with the application model in ASP.NET Core

Article • 06/17/2024

By Steve Smith

ASP.NET Core MVC defines an *application model* representing the components of an MVC app. Read and manipulate this model to modify how MVC elements behave. By default, MVC follows certain conventions to determine which classes are considered controllers, which methods on those classes are actions, and how parameters and routing behave. Customize this behavior to suit an app's needs by creating custom conventions and applying them globally or as attributes.

Models and Providers (`IApplicationModelProvider`)

The ASP.NET Core MVC application model includes both abstract interfaces and concrete implementation classes that describe an MVC application. This model is the result of MVC discovering the app's controllers, actions, action parameters, routes, and filters according to default conventions. By working with the application model, modify an app to follow different conventions from the default MVC behavior. The parameters, names, routes, and filters are all used as configuration data for actions and controllers.

The ASP.NET Core MVC Application Model has the following structure:

- ApplicationModel
  - Controllers (ControllerModel)
    - Actions (ActionModel)
      - Parameters (ParameterModel)

Each level of the model has access to a common `Properties` collection, and lower levels can access and overwrite property values set by higher levels in the hierarchy. The properties are persisted to the ActionDescriptor.Properties when the actions are created. Then when a request is being handled, any properties a convention added or modified can be accessed through ActionContext.ActionDescriptor. Using properties is a great way to configure filters, model binders, and other app model aspects on a per-action basis.

> **Note**

The ActionDescriptor.Properties collection isn't thread safe (for writes) after app startup. Conventions are the best way to safely add data to this collection.

ASP.NET Core MVC loads the application model using a provider pattern, defined by the IApplicationModelProvider interface. This section covers some of the internal implementation details of how this provider functions. Use of the provider pattern is an advanced subject, primarily for framework use. Most apps should use conventions, not the provider pattern.

Implementations of the IApplicationModelProvider interface "wrap" one another, where each implementation calls OnProvidersExecuting in ascending order based on its Order property. The OnProvidersExecuted method is then called in reverse order. The framework defines several providers:

First (`Order=-1000`):

- `DefaultApplicationModelProvider`

Then (`Order=-990`):

- `AuthorizationApplicationModelProvider`
- `CorsApplicationModelProvider`

> ⓘ Note
>
> The order in which two providers with the same value for `Order` are called is undefined and shouldn't be relied upon.

> ⓘ Note
>
> IApplicationModelProvider is an advanced concept for framework authors to extend. In general, apps should use conventions, and frameworks should use providers. The key distinction is that providers always run before conventions.

The `DefaultApplicationModelProvider` establishes many of the default behaviors used by ASP.NET Core MVC. Its responsibilities include:

- Adding global filters to the context
- Adding controllers to the context
- Adding public controller methods as actions
- Adding action method parameters to the context

- Applying route and other attributes

Some built-in behaviors are implemented by the `DefaultApplicationModelProvider`. This provider is responsible for constructing the ControllerModel, which in turn references ActionModel, PropertyModel, and ParameterModel instances. The `DefaultApplicationModelProvider` class is an internal framework implementation detail that may change in the future.

The `AuthorizationApplicationModelProvider` is responsible for applying the behavior associated with the AuthorizeFilter and AllowAnonymousFilter attributes. For more information, see Simple authorization in ASP.NET Core.

The `CorsApplicationModelProvider` implements behavior associated with IEnableCorsAttribute and IDisableCorsAttribute. For more information, see Enable Cross-Origin Requests (CORS) in ASP.NET Core.

Information on the framework's internal providers described in this section aren't available via the .NET API browser. However, the providers may be inspected in the ASP.NET Core reference source (dotnet/aspnetcore GitHub repository) . Use GitHub search to find the providers by name and select the version of the source with the **Switch branches/tags** dropdown list.

Conventions

The application model defines convention abstractions that provide a simpler way to customize the behavior of the models than overriding the entire model or provider. These abstractions are the recommended way to modify an app's behavior. Conventions provide a way to write code that dynamically applies customizations. While filters provide a means of modifying the framework's behavior, customizations permit control over how the whole app works together.

The following conventions are available:

- IApplicationModelConvention
- IControllerModelConvention
- IActionModelConvention
- IParameterModelConvention

Conventions are applied by adding them to MVC options or by implementing attributes and applying them to controllers, actions, or action parameters (similar to filters).Unlike filters, conventions are only executed when the app is starting, not as part of each request.

> **Note**
>
> For information on Razor Pages route and application model provider conventions, see Razor Pages route and app conventions in ASP.NET Core.

Modify the `ApplicationModel`

The following convention is used to add a property to the application model:

C#

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class ApplicationDescription : IApplicationModelConvention
    {
        private readonly string _description;

        public ApplicationDescription(string description)
        {
            _description = description;
        }

        public void Apply(ApplicationModel application)
        {
            application.Properties["description"] = _description;
        }
    }
}
```

Application model conventions are applied as options when MVC is added in `Startup.ConfigureServices`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Conventions.Add(new ApplicationDescription("My Application
Description"));
        options.Conventions.Add(new NamespaceRoutingConvention());
    });
}
```

Properties are accessible from the ActionDescriptor.Properties collection within controller actions:

C#

```
public class AppModelController : Controller
{
    public string Description()
    {
        return "Description: " +
ControllerContext.ActionDescriptor.Properties["description"];
    }
}
```

Modify the `ControllerModel` description

The controller model can also include custom properties. Custom properties override existing properties with the same name specified in the application model. The following convention attribute adds a description at the controller level:

C#

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class ControllerDescriptionAttribute : Attribute,
IControllerModelConvention
    {
        private readonly string _description;

        public ControllerDescriptionAttribute(string description)
        {
            _description = description;
        }

        public void Apply(ControllerModel controllerModel)
        {
            controllerModel.Properties["description"] = _description;
        }
    }
}
```

This convention is applied as an attribute on a controller:

C#

```
[ControllerDescription("Controller Description")]
public class DescriptionAttributesController : Controller
{
    public string Index()
    {
        return "Description: " +
ControllerContext.ActionDescriptor.Properties["description"];
    }
```

Modify the `ActionModel` description

A separate attribute convention can be applied to individual actions, overriding behavior already applied at the application or controller level:

C#

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class ActionDescriptionAttribute : Attribute,
IActionModelConvention
    {
        private readonly string _description;

        public ActionDescriptionAttribute(string description)
        {
            _description = description;
        }

        public void Apply(ActionModel actionModel)
        {
            actionModel.Properties["description"] = _description;
        }
    }
}
```

Applying this to an action within the controller demonstrates how it overrides the controller-level convention:

C#

```
[ControllerDescription("Controller Description")]
public class DescriptionAttributesController : Controller
{
    public string Index()
    {
```

```
        return "Description: " +
ControllerContext.ActionDescriptor.Properties["description"];
    }

    [ActionDescription("Action Description")]
    public string UseActionDescriptionAttribute()
    {
        return "Description: " +
ControllerContext.ActionDescriptor.Properties["description"];
    }
}
```

Modify the `ParameterModel`

The following convention can be applied to action parameters to modify their BindingInfo. The following convention requires that the parameter be a route parameter. Other potential binding sources, such as query string values, are ignored:

C#

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;
using Microsoft.AspNetCore.Mvc.ModelBinding;

namespace AppModelSample.Conventions
{
    public class MustBeInRouteParameterModelConvention : Attribute,
IParameterModelConvention
    {
        public void Apply(ParameterModel model)
        {
            if (model.BindingInfo == null)
            {
                model.BindingInfo = new BindingInfo();
            }
            model.BindingInfo.BindingSource = BindingSource.Path;
        }
    }
}
```

The attribute may be applied to any action parameter:

C#

```
public class ParameterModelController : Controller
{
    // Will bind:  /ParameterModel/GetById/123
    // WON'T bind: /ParameterModel/GetById?id=123
    public string GetById([MustBeInRouteParameterModelConvention]int id)
```

```
    {
        return $"Bound to id: {id}";
    }
}
```

To apply the convention to all action parameters, add the `MustBeInRouteParameterModelConvention` to MvcOptions in `Startup.ConfigureServices`:

C#

```
options.Conventions.Add(new MustBeInRouteParameterModelConvention());
```

Modify the `ActionModel` name

The following convention modifies the ActionModel to update the *name* of the action to which it's applied. The new name is provided as a parameter to the attribute. This new name is used by routing, so it affects the route used to reach this action method:

C#

```
using System;
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class CustomActionNameAttribute : Attribute,
IActionModelConvention
    {
        private readonly string _actionName;

        public CustomActionNameAttribute(string actionName)
        {
            _actionName = actionName;
        }

        public void Apply(ActionModel actionModel)
        {
            // this name will be used by routing
            actionModel.ActionName = _actionName;
        }
    }
}
```

This attribute is applied to an action method in the `HomeController`:

C#

```
// Route: /Home/MyCoolAction
[CustomActionName("MyCoolAction")]
public string SomeName()
{
    return ControllerContext.ActionDescriptor.ActionName;
}
```

Even though the method name is `SomeName`, the attribute overrides the MVC convention of using the method name and replaces the action name with `MyCoolAction`. Thus, the route used to reach this action is `/Home/MyCoolAction`.

> ⓘ **Note**
>
> This example in this section is essentially the same as using the built-in ActionNameAttribute.

Custom routing convention

Use an IApplicationModelConvention to customize how routing works. For example, the following convention incorporates controllers' namespaces into their routes, replacing `.` in the namespace with `/` in the route:

C#

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;
using System.Linq;

namespace AppModelSample.Conventions
{
    public class NamespaceRoutingConvention : IApplicationModelConvention
    {
        public void Apply(ApplicationModel application)
        {
            foreach (var controller in application.Controllers)
            {
                var hasAttributeRouteModels = controller.Selectors
                    .Any(selector => selector.AttributeRouteModel != null);

                if (!hasAttributeRouteModels
                    && controller.ControllerName.Contains("Namespace")) //
affect one controller in this sample
                {
                    // Replace the . in the namespace with a / to create the
attribute route
                    // Ex: MySite.Admin namespace will correspond to
MySite/Admin attribute route
```

```
                    // Then attach [controller], [action] and optional {id?}
token.
                    // [Controller] and [action] is replaced with the
controller and action
                    // name to generate the final template
                    controller.Selectors[0].AttributeRouteModel = new
AttributeRouteModel()
                    {
                        Template =
controller.ControllerType.Namespace.Replace('.', '/') +
"/[controller]/[action]/{id?}"
                    };
                }
            }

            // You can continue to put attribute route templates for the
controller actions depending on the way you want them to behave
        }
    }
}
```

The convention is added as an option in `Startup.ConfigureServices`:

C#

```
public void ConfigureServices(IServiceCollection services)
{
    services.AddMvc(options =>
    {
        options.Conventions.Add(new ApplicationDescription("My Application
Description"));
        options.Conventions.Add(new NamespaceRoutingConvention());
    });
}
```

Tip

Add conventions to **middleware** via **MvcOptions** using the following approach. The `{CONVENTION}` placeholder is the convention to add:

C#

```
services.Configure<MvcOptions>(c => c.Conventions.Add({CONVENTION}));
```

The following example applies a convention to routes that aren't using attribute routing where the controller has `Namespace` in its name:

C#

```
using Microsoft.AspNetCore.Mvc;

namespace AppModelSample.Controllers
{
    public class NamespaceRoutingController : Controller
    {
        // using NamespaceRoutingConvention
        // route: /AppModelSample/Controllers/NamespaceRouting/Index
        public string Index()
        {
            return "This demonstrates namespace routing.";
        }
    }
}
```

Use `ApiExplorer` to document an app

The application model exposes an ApiExplorerModel property at each level that can be used to traverse the app's structure. This can be used to generate help pages for web APIs using tools like Swagger. The `ApiExplorer` property exposes an IsVisible property that can be set to specify which parts of the app's model should be exposed. Configure this setting using a convention:

C#

```
using Microsoft.AspNetCore.Mvc.ApplicationModels;

namespace AppModelSample.Conventions
{
    public class EnableApiExplorerApplicationConvention :
IApplicationModelConvention
    {
        public void Apply(ApplicationModel application)
        {
            application.ApiExplorer.IsVisible = true;
        }
    }
}
```

Using this approach (and additional conventions if required), API visibility is enabled or disabled at any level within an app.

Areas in ASP.NET Core

Article • 06/17/2024

By Dhananjay Kumar and Rick Anderson

Areas are an ASP.NET feature used to organize related functionality into a group as a separate:

- Namespace for routing.
- Folder structure for views and Razor Pages.

Using areas creates a hierarchy for the purpose of routing by adding another route parameter, `area`, to `controller` and `action` or a Razor Page `page`.

Areas provide a way to partition an ASP.NET Core Web app into smaller functional groups, each with its own set of Razor Pages, controllers, views, and models. An area is effectively a structure inside an app. In an ASP.NET Core web project, logical components like Pages, Model, Controller, and View are kept in different folders. The ASP.NET Core runtime uses naming conventions to create the relationship between these components. For a large app, it may be advantageous to partition the app into separate high level areas of functionality. For instance, an e-commerce app with multiple business units, such as checkout, billing, and search. Each of these units have their own area to contain views, controllers, Razor Pages, and models.

Consider using Areas in a project when:

- The app is made of multiple high-level functional components that can be logically separated.
- You want to partition the app so that each functional area can be worked on independently.

If you're using Razor Pages, see Areas with Razor Pages in this document.

Areas for controllers with views

A typical ASP.NET Core web app using areas, controllers, and views contains the following:

- An Area folder structure.
- Controllers with the [Area] attribute to associate the controller with the area:

```
C#
```

```
[Area("Products")]
public class ManageController : Controller
{
```

- The area route added to Program.cs:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapControllerRoute(
    name: "MyArea",
    pattern: "{area:exists}/{controller=Home}/{action=Index}/{id?}");

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

Area folder structure

Consider an app that has two logical groups, *Products* and *Services*. Using areas, the folder structure would be similar to the following:

- Project name
  - Areas
    - Products
      - Controllers
        - HomeController.cs
        - ManageController.cs

        - Views
            - Home
                - Index.cshtml
            - Manage
                - Index.cshtml
                - About.cshtml
    - Services
        - Controllers
            - HomeController.cs
        - Views
            - Home
                - Index.cshtml

While the preceding layout is typical when using Areas, only the view files are required to use this folder structure. View discovery searches for a matching area view file in the following order:

```text
/Areas/<Area-Name>/Views/<Controller-Name>/<Action-Name>.cshtml
/Areas/<Area-Name>/Views/Shared/<Action-Name>.cshtml
/Views/Shared/<Action-Name>.cshtml
/Pages/Shared/<Action-Name>.cshtml
```

Associate the controller with an Area

Area controllers are designated with the [Area] attribute:

```C#
using Microsoft.AspNetCore.Mvc;
using Microsoft.Docs.Samples;

namespace MVCareas.Areas.Products.Controllers;

[Area("Products")]
public class ManageController : Controller
{
    public IActionResult Index()
    {
        ViewData["routeInfo"] = ControllerContext.MyDisplayRouteInfo();
        return View();
    }

    public IActionResult About()
    {
```

```
        ViewData["routeInfo"] = ControllerContext.MyDisplayRouteInfo();
        return View();
    }
}
```

Add Area route

Area routes typically use conventional routing rather than attribute routing. Conventional routing is order-dependent. In general, routes with areas should be placed earlier in the route table as they're more specific than routes without an area.

`{area:...}` can be used as a token in route templates if url space is uniform across all areas:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapControllerRoute(
    name: "MyArea",
    pattern: "{area:exists}/{controller=Home}/{action=Index}/{id?}");

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

In the preceding code, `exists` applies a constraint that the route must match an area. Using `{area:...}` with `MapControllerRoute`:

- Is the least complicated mechanism to adding routing to areas.

- Matches all controllers with the `[Area("Area name")]` attribute.

The following code uses MapAreaControllerRoute to create two named area routes:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapAreaControllerRoute(
    name: "MyAreaProducts",
    areaName: "Products",
    pattern: "Products/{controller=Home}/{action=Index}/{id?}");

app.MapAreaControllerRoute(
    name: "MyAreaServices",
    areaName: "Services",
    pattern: "Services/{controller=Home}/{action=Index}/{id?}");

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

For more information, see Area routing.

Link generation with MVC areas

The following code from the sample download shows link generation with the area specified:

CSHTML

```
<li>Anchor Tag Helper links</li>
<ul>
    <li>
        <a asp-area="Products" asp-controller="Home" asp-action="About">
            Products/Home/About
        </a>
    </li>
    <li>
        <a asp-area="Services" asp-controller="Home" asp-action="About">
            Services About
        </a>
    </li>
    <li>
        <a asp-area="" asp-controller="Home" asp-action="About">
            /Home/About
        </a>
    </li>
</ul>
<li>Html.ActionLink generated links</li>
<ul>
    <li>
        @Html.ActionLink("Product/Manage/About", "About", "Manage",
                                                 new { area = "Products" })
    </li>
</ul>
<li>Url.Action generated links</li>
<ul>
    <li>
        <a href='@Url.Action("About", "Manage", new { area = "Products" })'>
            Products/Manage/About
        </a>
    </li>
</ul>
```

The sample download includes a partial view that contains:

- The preceding links.
- Links similar to the preceding except `area` is not specified.

The partial view is referenced in the layout file, so every page in the app displays the generated links. The links generated without specifying the area are only valid when referenced from a page in the same area and controller.

When the area or controller is not specified, routing depends on the ambient values. The current route values of the current request are considered ambient values for link generation. In many cases for the sample app, using the ambient values generates incorrect links with the markup that doesn't specify the area.

For more information, see Routing to controller actions.

Shared layout for Areas using the _ViewStart.cshtml file

To share a common layout for the entire app, keep the *_ViewStart.cshtml* in the application root folder. For more information, see Layout in ASP.NET Core

Application root folder

The application root folder is the folder containing the `Program.cs` file in a web app created with the ASP.NET Core templates.

_ViewImports.cshtml

/Views/_ViewImports.cshtml, for MVC, and */Pages/_ViewImports.cshtml* for Razor Pages, is not imported to views in areas. Use one of the following approaches to provide view imports to all views:

- Add *_ViewImports.cshtml* to the application root folder. A *_ViewImports.cshtml* in the application root folder will apply to all views in the app.
- Copy the *_ViewImports.cshtml* file to the appropriate view folder under areas. For example, a Razor Pages app created with individual user accounts has a *_ViewImports.cshtml* file in the following folders:
  - */Areas/Identity/Pages/_ViewImports.cshtml*
  - */Pages/_ViewImports.cshtml*

The *_ViewImports.cshtml* file typically contains Tag Helpers imports, `@using`, and `@inject` statements. For more information, see Importing Shared Directives.

Change default area folder where views are stored

The following code changes the default area folder from `"Areas"` to `"MyAreas"`:

C#

```
using Microsoft.AspNetCore.Mvc.Razor;

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.Configure<RazorViewEngineOptions>(options =>
{
    options.AreaViewLocationFormats.Clear();

options.AreaViewLocationFormats.Add("/MyAreas/{2}/Views/{1}/{0}.cshtml");

options.AreaViewLocationFormats.Add("/MyAreas/{2}/Views/Shared/{0}.cshtml");
    options.AreaViewLocationFormats.Add("/Views/Shared/{0}.cshtml");
});
```

```
builder.Services.AddControllersWithViews();

var app = builder.Build();

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/Home/Error");
    app.UseHsts();
}

app.UseHttpsRedirection();
app.UseStaticFiles();

app.UseRouting();

app.UseAuthorization();

app.MapControllerRoute(
    name: "MyArea",
    pattern: "{area:exists}/{controller=Home}/{action=Index}/{id?}");

app.MapControllerRoute(
    name: "default",
    pattern: "{controller=Home}/{action=Index}/{id?}");

app.Run();
```

Areas with Razor Pages

Areas with Razor Pages require an `Areas/<area name>/Pages` folder in the root of the app. The following folder structure is used with the sample app:

- Project name
  - Areas
    - Products
      - Pages
        - _ViewImports
        - About
        - Index

- Services
  - Pages
    - Manage
      - About
      - Index

Link generation with Razor Pages and areas

The following code from the sample download shows link generation with the area specified (for example, `asp-area="Products"`):

CSHTML

```
<li>Anchor Tag Helper links</li>
<ul>
    <li>
        <a asp-area="Products" asp-page="/About">
            Products/About
        </a>
    </li>
    <li>
        <a asp-area="Services" asp-page="/Manage/About">
            Services/Manage/About
        </a>
    </li>
    <li>
        <a asp-area="" asp-page="/About">
            /About
        </a>
    </li>
</ul>
<li>Url.Page generated links</li>
<ul>
    <li>
        <a href='@Url.Page("/Manage/About", new { area = "Services" })'>
            Services/Manage/About
        </a>
    </li>
    <li>
        <a href='@Url.Page("/About", new { area = "Products" })'>
            Products/About
        </a>
    </li>
</ul>
```

The sample download includes a partial view that contains the preceding links and the same links without specifying the area. The partial view is referenced in the layout file, so every page in the app displays the generated links. The links generated without specifying the area are only valid when referenced from a page in the same area.

When the area is not specified, routing depends on the *ambient* values. The current route values of the current request are considered ambient values for link generation. In many cases for the sample app, using the ambient values generates incorrect links. For example, consider the links generated from the following code:

CSHTML

```
<li>
    <a asp-page="/Manage/About">
        Services/Manage/About
    </a>
</li>
<li>
    <a asp-page="/About">
        /About
    </a>
</li>
```

For the preceding code:

- The link generated from `<a asp-page="/Manage/About">` is correct only when the last request was for a page in `Services` area. For example, `/Services/Manage/`, `/Services/Manage/Index`, or `/Services/Manage/About`.
- The link generated from `<a asp-page="/About">` is correct only when the last request was for a page in `/Home`.
- The code is from the sample download.

Import namespace and Tag Helpers with _ViewImports file

A *_ViewImports.cshtml* file can be added to each area *Pages* folder to import the namespace and Tag Helpers to each Razor Page in the folder.

Consider the *Services* area of the sample code, which doesn't contain a *_ViewImports.cshtml* file. The following markup shows the */Services/Manage/About* Razor Page:

CSHTML

```
@page
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
@model RPareas.Areas.Services.Pages.Manage.AboutModel
@{
    ViewData["Title"] = "Srv Mng About";
}
```

```
<div>
  ViewData["routeInfo"]:  @ViewData["routeInfo"]
</div>

<a asp-area="Products" asp-page="/Index">
    Products/Index
</a>
```

In the preceding markup:

- The fully qualified class name must be used to specify the model (`@model RPareas.Areas.Services.Pages.Manage.AboutModel`).
- Tag Helpers are enabled by `@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers`

In the sample download, the Products area contains the following *_ViewImports.cshtml* file:

CSHTML

```
@namespace RPareas.Areas.Products.Pages
@addTagHelper *, Microsoft.AspNetCore.Mvc.TagHelpers
```

The following markup shows the */Products/About* Razor Page:

CSHTML

```
@page
@model AboutModel
@{
    ViewData["Title"] = "Prod About";
}
```

In the preceding file, the namespace and `@addTagHelper` directive is imported to the file by the *Areas/Products/Pages/_ViewImports.cshtml* file.

For more information, see Managing Tag Helper scope and Importing Shared Directives.

Shared layout for Razor Pages Areas

To share a common layout for the entire app, move the *_ViewStart.cshtml* to the application root folder.

Publishing Areas

All *.cshtml files and files within the *wwwroot* directory are published to output when `<Project Sdk="Microsoft.NET.Sdk.Web">` is included in the *.csproj file.

Add MVC Area with Visual Studio

In Solution Explorer, right click the project and select **ADD** > **New Scaffolded Item**, then select **MVC Area**.

Additional resources

- View or download sample code (how to download). The download sample provides a basic app for testing areas.
- MyDisplayRouteInfo and ToCtxString are provided by the Rick.Docs.Samples.RouteInfo NuGet package. The methods display `Controller` and `Razor Page` route information.

Filters in ASP.NET Core

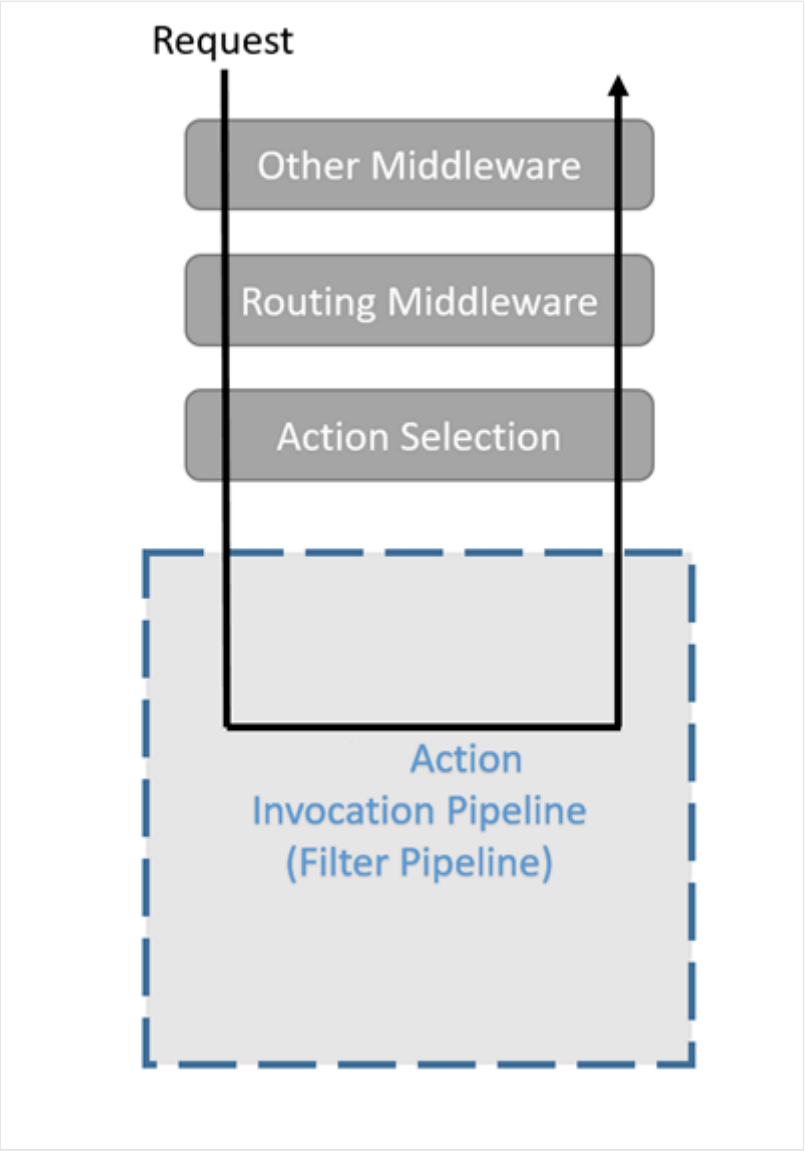
Article • 06/17/2024

By Kirk Larkin, Rick Anderson, Tom Dykstra, and Steve Smith

Filters in ASP.NET Core allow code to run before or after specific stages in the request processing pipeline.

Built-in filters handle tasks such as:

- Authorization, preventing access to resources a user isn't authorized for.
- Response caching, short-circuiting the request pipeline to return a cached response.



Custom filters can be created to handle cross-cutting concerns. Examples of cross-cutting concerns include error handling, caching, configuration, authorization, and logging. Filters avoid duplicating code. For example, an error handling exception filter could consolidate error handling.

This document applies to Razor Pages, API controllers, and controllers with views. Filters don't work directly with Razor components. A filter can only indirectly affect a component when:

- The component is embedded in a page or view.
- The page or controller and view uses the filter.

How filters work

Filters run within the *ASP.NET Core action invocation pipeline*, sometimes referred to as the *filter pipeline*. The filter pipeline runs after ASP.NET Core selects the action to execute:

Filter types

Each filter type is executed at a different stage in the filter pipeline:

- Authorization filters:
  - Run first.
  - Determine whether the user is authorized for the request.
  - Short-circuit the pipeline if the request is not authorized.
- Resource filters:
  - Run after authorization.
  - OnResourceExecuting runs code before the rest of the filter pipeline. For example, `OnResourceExecuting` runs code before model binding.
  - OnResourceExecuted runs code after the rest of the pipeline has completed.
- Action filters:
  - Run immediately before and after an action method is called.
  - Can change the arguments passed into an action.

    - Can change the result returned from the action.
    - Are **not** supported in Razor Pages.

- Endpoint filters:
    - Run immediately before and after an action method is called.
    - Can change the arguments passed into an action.
    - Can change the result returned from the action.
    - Are **not** supported in Razor Pages.
    - Can be invoked on both actions and route handler-based endpoints.

- Exception filters apply global policies to unhandled exceptions that occur before the response body has been written to.

- Result filters:
    - Run immediately before and after the execution of action results.
    - Run only when the action method executes successfully.
    - Are useful for logic that must surround view or formatter execution.

The following diagram shows how filter types interact in the filter pipeline:

Razor Pages also support Razor Page filters, which run before and after a Razor Page handler.

Implementation

Filters support both synchronous and asynchronous implementations through different interface definitions.

Synchronous filters run before and after their pipeline stage. For example, OnActionExecuting is called before the action method is called. OnActionExecuted is called after the action method returns:

```
C#
```

```
public class SampleActionFilter : IActionFilter
{
    public void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
    }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
    }
}
```

Asynchronous filters define an `On-Stage-ExecutionAsync` method. For example, OnActionExecutionAsync:

```
C#
```

```
public class SampleAsyncActionFilter : IAsyncActionFilter
{
    public async Task OnActionExecutionAsync(
        ActionExecutingContext context, ActionExecutionDelegate next)
    {
        // Do something before the action executes.
        await next();
        // Do something after the action executes.
    }
}
```

In the preceding code, the `SampleAsyncActionFilter` has an ActionExecutionDelegate, `next`, which executes the action method.

Multiple filter stages

Interfaces for multiple filter stages can be implemented in a single class. For example, the ActionFilterAttribute class implements:

- Synchronous: IActionFilter and IResultFilter
- Asynchronous: IAsyncActionFilter and IAsyncResultFilter
- IOrderedFilter

Implement **either** the synchronous or the async version of a filter interface, **not** both. The runtime checks first to see if the filter implements the async interface, and if so, it calls that. If not, it calls the synchronous interface's method(s). If both asynchronous and synchronous interfaces are implemented in one class, only the async method is called. When using abstract classes like ActionFilterAttribute, override only the synchronous methods or the asynchronous methods for each filter type.

Built-in filter attributes

ASP.NET Core includes built-in attribute-based filters that can be subclassed and customized. For example, the following result filter adds a header to the response:

C#

```
public class ResponseHeaderAttribute : ActionFilterAttribute
{
    private readonly string _name;
    private readonly string _value;

    public ResponseHeaderAttribute(string name, string value) =>
        (_name, _value) = (name, value);

    public override void OnResultExecuting(ResultExecutingContext context)
    {
        context.HttpContext.Response.Headers.Add(_name, _value);

        base.OnResultExecuting(context);
    }
}
```

Attributes allow filters to accept arguments, as shown in the preceding example. Apply the `ResponseHeaderAttribute` to a controller or action method and specify the name and value of the HTTP header:

C#

```
[ResponseHeader("Filter-Header", "Filter Value")]
public class ResponseHeaderController : ControllerBase
{
    public IActionResult Index() =>
        Content("Examine the response headers using the F12 developer
tools.");

    // ...
```

Use a tool such as the browser developer tools to examine the headers. Under **Response Headers**, `filter-header: Filter Value` is displayed.

The following code applies `ResponseHeaderAttribute` to both a controller and an action:

```
C#

[ResponseHeader("Filter-Header", "Filter Value")]
public class ResponseHeaderController : ControllerBase
{
    public IActionResult Index() =>
        Content("Examine the response headers using the F12 developer
tools.");

    // ...

    [ResponseHeader("Another-Filter-Header", "Another Filter Value")]
    public IActionResult Multiple() =>
        Content("Examine the response headers using the F12 developer
tools.");
}
```

Responses from the `Multiple` action include the following headers:

- `filter-header: Filter Value`
- `another-filter-header: Another Filter Value`

Several of the filter interfaces have corresponding attributes that can be used as base classes for custom implementations.

Filter attributes:

- ActionFilterAttribute
- ExceptionFilterAttribute
- ResultFilterAttribute
- FormatFilterAttribute
- ServiceFilterAttribute
- TypeFilterAttribute

Filters cannot be applied to Razor Page handler methods. They can be applied either to the Razor Page model or globally.

Filter scopes and order of execution

A filter can be added to the pipeline at one of three *scopes*:

- Using an attribute on a controller or Razor Page.
- Using an attribute on a controller action. Filter attributes cannot be applied to Razor Pages handler methods.
- Globally for all controllers, actions, and Razor Pages as shown in the following code:

```
C#

var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.AddControllersWithViews(options =>
{
    options.Filters.Add<GlobalSampleActionFilter>();
});
```

Default order of execution

When there are multiple filters for a particular stage of the pipeline, scope determines the default order of filter execution. Global filters surround class filters, which in turn surround method filters.

As a result of filter nesting, the *after* code of filters runs in the reverse order of the *before* code. The filter sequence:

- The *before* code of global filters.
  - The *before* code of controller filters.
    - The *before* code of action method filters.
    - The *after* code of action method filters.
  - The *after* code of controller filters.
- The *after* code of global filters.

The following example illustrates the order in which filter methods run for synchronous action filters:

Expand table

Sequence	Filter scope	Filter method
1	Global	`OnActionExecuting`
2	Controller	`OnActionExecuting`
3	Action	`OnActionExecuting`

Sequence	Filter scope	Filter method
4	Action	`OnActionExecuted`
5	Controller	`OnActionExecuted`
6	Global	`OnActionExecuted`

Controller level filters

Every controller that inherits from Controller includes the OnActionExecuting, OnActionExecutionAsync, and OnActionExecuted methods. These methods wrap the filters that run for a given action:

- `OnActionExecuting` runs before any of the action's filters.
- `OnActionExecuted` runs after all of the action's filters.
- `OnActionExecutionAsync` runs before any of the action's filters. Code after a call to `next` runs after the action's filters.

The following `ControllerFiltersController` class:

- Applies the `SampleActionFilterAttribute` (`[SampleActionFilter]`) to the controller.
- Overrides `OnActionExecuting` and `OnActionExecuted`.

C#

```
[SampleActionFilter]
public class ControllerFiltersController : Controller
{
    public override void OnActionExecuting(ActionExecutingContext context)
    {
        Console.WriteLine(
            $"- {nameof(ControllerFiltersController)}.
{nameof(OnActionExecuting)}");

        base.OnActionExecuting(context);
    }

    public override void OnActionExecuted(ActionExecutedContext context)
    {
        Console.WriteLine(
            $"- {nameof(ControllerFiltersController)}.
{nameof(OnActionExecuted)}");

        base.OnActionExecuted(context);
    }

    public IActionResult Index()
```

```
    {
        Console.WriteLine(
            $"- {nameof(ControllerFiltersController)}.{nameof(Index)}");

        return Content("Check the Console.");
    }
}
```

Navigating to `https://localhost:<port>/ControllerFilters` runs the following code:

- `ControllerFiltersController.OnActionExecuting`
  - `GlobalSampleActionFilter.OnActionExecuting`
    - `SampleActionFilterAttribute.OnActionExecuting`
      - `ControllerFiltersController.Index`
    - `SampleActionFilterAttribute.OnActionExecuted`
  - `GlobalSampleActionFilter.OnActionExecuted`
- `ControllerFiltersController.OnActionExecuted`

Controller level filters set the Order property to `int.MinValue`. Controller level filters can **not** be set to run after filters applied to methods. Order is explained in the next section.

For Razor Pages, see Implement Razor Page filters by overriding filter methods.

Override the default order

The default sequence of execution can be overridden by implementing IOrderedFilter. `IOrderedFilter` exposes the Order property that takes precedence over scope to determine the order of execution. A filter with a lower `Order` value:

- Runs the *before* code before that of a filter with a higher value of `Order`.
- Runs the *after* code after that of a filter with a higher `Order` value.

In the Controller level filters example, `GlobalSampleActionFilter` has global scope so it runs before `SampleActionFilterAttribute`, which has controller scope. To make `SampleActionFilterAttribute` run first, set its order to `int.MinValue`:

C#

```
[SampleActionFilter(Order = int.MinValue)]
public class ControllerFiltersController : Controller
{
    // ...
}
```

To make the global filter `GlobalSampleActionFilter` run first, set its `Order` to `int.MinValue`:

```
C#

builder.Services.AddControllersWithViews(options =>
{
    options.Filters.Add<GlobalSampleActionFilter>(int.MinValue);
});
```

Cancellation and short-circuiting

The filter pipeline can be short-circuited by setting the Result property on the ResourceExecutingContext parameter provided to the filter method. For example, the following Resource filter prevents the rest of the pipeline from executing:

```
C#

public class ShortCircuitingResourceFilterAttribute : Attribute,
IResourceFilter
{
    public void OnResourceExecuting(ResourceExecutingContext context)
    {
        context.Result = new ContentResult
        {
            Content = nameof(ShortCircuitingResourceFilterAttribute)
        };
    }

    public void OnResourceExecuted(ResourceExecutedContext context) { }
}
```

In the following code, both the `[ShortCircuitingResourceFilter]` and the `[ResponseHeader]` filter target the `Index` action method. The `ShortCircuitingResourceFilterAttribute` filter:

- Runs first, because it's a Resource Filter and `ResponseHeaderAttribute` is an Action Filter.
- Short-circuits the rest of the pipeline.

Therefore the `ResponseHeaderAttribute` filter never runs for the `Index` action. This behavior would be the same if both filters were applied at the action method level, provided the `ShortCircuitingResourceFilterAttribute` ran first. The `ShortCircuitingResourceFilterAttribute` runs first because of its filter type:

C#

```
[ResponseHeader("Filter-Header", "Filter Value")]
public class ShortCircuitingController : Controller
{
    [ShortCircuitingResourceFilter]
    public IActionResult Index() =>
        Content($"- {nameof(ShortCircuitingController)}.{nameof(Index)}");
}
```

Dependency injection

Filters can be added by type or by instance. If an instance is added, that instance is used for every request. If a type is added, it's type-activated. A type-activated filter means:

- An instance is created for each request.
- Any constructor dependencies are populated by dependency injection (DI).

Filters that are implemented as attributes and added directly to controller classes or action methods cannot have constructor dependencies provided by dependency injection (DI). Constructor dependencies cannot be provided by DI because attributes must have their constructor parameters supplied where they're applied.

The following filters support constructor dependencies provided from DI:

- ServiceFilterAttribute
- TypeFilterAttribute
- IFilterFactory implemented on the attribute.

The preceding filters can be applied to a controller or an action.

Loggers are available from DI. However, avoid creating and using filters purely for logging purposes. The built-in framework logging typically provides what's needed for logging. Logging added to filters:

- Should focus on business domain concerns or behavior specific to the filter.
- Should **not** log actions or other framework events. The built-in filters already log actions and framework events.

ServiceFilterAttribute

Service filter implementation types are registered in `Program.cs`. A ServiceFilterAttribute retrieves an instance of the filter from DI.

The following code shows the `LoggingResponseHeaderFilterService` class, which uses DI:

C#

```
public class LoggingResponseHeaderFilterService : IResultFilter
{
    private readonly ILogger _logger;

    public LoggingResponseHeaderFilterService(
            ILogger<LoggingResponseHeaderFilterService> logger) =>
        _logger = logger;

    public void OnResultExecuting(ResultExecutingContext context)
    {
        _logger.LogInformation(
            $"- {nameof(LoggingResponseHeaderFilterService)}.
{nameof(OnResultExecuting)}");

        context.HttpContext.Response.Headers.Add(
            nameof(OnResultExecuting),
nameof(LoggingResponseHeaderFilterService));
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
        _logger.LogInformation(
            $"- {nameof(LoggingResponseHeaderFilterService)}.
{nameof(OnResultExecuted)}");
    }
}
```

In the following code, `LoggingResponseHeaderFilterService` is added to the DI container:

C#

```
builder.Services.AddScoped<LoggingResponseHeaderFilterService>();
```

In the following code, the `ServiceFilter` attribute retrieves an instance of the `LoggingResponseHeaderFilterService` filter from DI:

C#

```
[ServiceFilter<LoggingResponseHeaderFilterService>]
public IActionResult WithServiceFilter() =>
    Content($"- {nameof(FilterDependenciesController)}.
{nameof(WithServiceFilter)}");
```

When using `ServiceFilterAttribute`, setting ServiceFilterAttribute.IsReusable:

- Provides a hint that the filter instance *may* be reused outside of the request scope it was created within. The ASP.NET Core runtime doesn't guarantee:
  - That a single instance of the filter will be created.
  - The filter will not be re-requested from the DI container at some later point.
- Shouldn't be used with a filter that depends on services with a lifetime other than singleton.

ServiceFilterAttribute implements IFilterFactory. `IFilterFactory` exposes the CreateInstance method for creating an IFilterMetadata instance. `CreateInstance` loads the specified type from DI.

TypeFilterAttribute

TypeFilterAttribute is similar to ServiceFilterAttribute, but its type isn't resolved directly from the DI container. It instantiates the type by using Microsoft.Extensions.DependencyInjection.ObjectFactory.

Because `TypeFilterAttribute` types aren't resolved directly from the DI container:

- Types that are referenced using the `TypeFilterAttribute` don't need to be registered with the DI container. They do have their dependencies fulfilled by the DI container.
- `TypeFilterAttribute` can optionally accept constructor arguments for the type.

When using `TypeFilterAttribute`, setting TypeFilterAttribute.IsReusable:

- Provides hint that the filter instance *may* be reused outside of the request scope it was created within. The ASP.NET Core runtime provides no guarantees that a single instance of the filter will be created.
- Should not be used with a filter that depends on services with a lifetime other than singleton.

The following example shows how to pass arguments to a type using `TypeFilterAttribute`:

C#

```
[TypeFilter(typeof(LoggingResponseHeaderFilter),
    Arguments = new object[] { "Filter-Header", "Filter Value" })]
public IActionResult WithTypeFilter() =>
    Content($"- {nameof(FilterDependenciesController)}.
{nameof(WithTypeFilter)}");
```

Authorization filters

Authorization filters:

- Are the first filters run in the filter pipeline.
- Control access to action methods.
- Have a before method, but no after method.

Custom authorization filters require a custom authorization framework. Prefer configuring the authorization policies or writing a custom authorization policy over writing a custom filter. The built-in authorization filter:

- Calls the authorization system.
- Does not authorize requests.

Do **not** throw exceptions within authorization filters:

- The exception will not be handled.
- Exception filters will not handle the exception.

Consider issuing a challenge when an exception occurs in an authorization filter.

Learn more about Authorization.

Resource filters

Resource filters:

- Implement either the IResourceFilter or IAsyncResourceFilter interface.
- Execution wraps most of the filter pipeline.
- Only Authorization filters run before resource filters.

Resource filters are useful to short-circuit most of the pipeline. For example, a caching filter can avoid the rest of the pipeline on a cache hit.

Resource filter examples:

- The short-circuiting resource filter shown previously.
- DisableFormValueModelBindingAttribute:
  - Prevents model binding from accessing the form data.
  - Used for large file uploads to prevent the form data from being read into memory.

Action filters

Action filters do **not** apply to Razor Pages. Razor Pages supports IPageFilter and IAsyncPageFilter. For more information, see Filter methods for Razor Pages.

Action filters:

- Implement either the IActionFilter or IAsyncActionFilter interface.
- Their execution surrounds the execution of action methods.

The following code shows a sample action filter:

C#

```
public class SampleActionFilter : IActionFilter
{
    public void OnActionExecuting(ActionExecutingContext context)
    {
        // Do something before the action executes.
    }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        // Do something after the action executes.
    }
}
```

The ActionExecutingContext provides the following properties:

- ActionArguments - enables reading the inputs to an action method.
- Controller - enables manipulating the controller instance.
- Result - setting `Result` short-circuits execution of the action method and subsequent action filters.

Throwing an exception in an action method:

- Prevents running of subsequent filters.
- Unlike setting `Result`, is treated as a failure instead of a successful result.

The ActionExecutedContext provides `Controller` and `Result` plus the following properties:

- Canceled - True if the action execution was short-circuited by another filter.
- Exception - Non-null if the action or a previously run action filter threw an exception. Setting this property to null:
  - Effectively handles the exception.

    - `Result` is executed as if it was returned from the action method.

For an `IAsyncActionFilter`, a call to the ActionExecutionDelegate:

- Executes any subsequent action filters and the action method.
- Returns `ActionExecutedContext`.

To short-circuit, assign Microsoft.AspNetCore.Mvc.Filters.ActionExecutingContext.Result to a result instance and don't call `next` (the `ActionExecutionDelegate`).

The framework provides an abstract ActionFilterAttribute that can be subclassed.

The `OnActionExecuting` action filter can be used to:

- Validate model state.
- Return an error if the state is invalid.

C#

```
public class ValidateModelAttribute : ActionFilterAttribute
{
    public override void OnActionExecuting(ActionExecutingContext context)
    {
        if (!context.ModelState.IsValid)
        {
            context.Result = new BadRequestObjectResult(context.ModelState);
        }
    }
}
```

> **Note**
>
> Controllers annotated with the `[ApiController]` attribute automatically validate model state and return a 400 response. For more information, see Automatic HTTP 400 responses.

The `OnActionExecuted` method runs after the action method:

- And can see and manipulate the results of the action through the Result property.
- Canceled is set to true if the action execution was short-circuited by another filter.
- Exception is set to a non-null value if the action or a subsequent action filter threw an exception. Setting `Exception` to null:
    - Effectively handles an exception.
    - `ActionExecutedContext.Result` is executed as if it were returned normally from the action method.

Exception filters

Exception filters:

- Implement IExceptionFilter or IAsyncExceptionFilter.
- Can be used to implement common error handling policies.

The following sample exception filter displays details about exceptions that occur when the app is in development:

C#

```
public class SampleExceptionFilter : IExceptionFilter
{
    private readonly IHostEnvironment _hostEnvironment;

    public SampleExceptionFilter(IHostEnvironment hostEnvironment) =>
        _hostEnvironment = hostEnvironment;

    public void OnException(ExceptionContext context)
    {
        if (!_hostEnvironment.IsDevelopment())
        {
            // Don't display exception details unless running in
Development.
            return;
        }

        context.Result = new ContentResult
        {
            Content = context.Exception.ToString()
        };
    }
}
```

The following code tests the exception filter:

C#

```
[TypeFilter<SampleExceptionFilter>]
public class ExceptionController : Controller
{
    public IActionResult Index() =>
        Content($"- {nameof(ExceptionController)}.{nameof(Index)}");
}
```

Exception filters:

- Don't have before and after events.

- Implement OnException or OnExceptionAsync.
- Handle unhandled exceptions that occur in Razor Page or controller creation, model binding, action filters, or action methods.
- Do **not** catch exceptions that occur in resource filters, result filters, or MVC result execution.

To handle an exception, set the ExceptionHandled property to `true` or assign the Result property. This stops propagation of the exception. An exception filter can't turn an exception into a "success". Only an action filter can do that.

Exception filters:

- Are good for trapping exceptions that occur within actions.
- Are not as flexible as error handling middleware.

Prefer middleware for exception handling. Use exception filters only where error handling *differs* based on which action method is called. For example, an app might have action methods for both API endpoints and for views/HTML. The API endpoints could return error information as JSON, while the view-based actions could return an error page as HTML.

Result filters

Result filters:

- Implement an interface:
  - IResultFilter or IAsyncResultFilter
  - IAlwaysRunResultFilter or IAsyncAlwaysRunResultFilter
- Their execution surrounds the execution of action results.

IResultFilter and IAsyncResultFilter

The following code shows a sample result filter:

C#

```
public class SampleResultFilter : IResultFilter
{
    public void OnResultExecuting(ResultExecutingContext context)
    {
        // Do something before the result executes.
    }

    public void OnResultExecuted(ResultExecutedContext context)
    {
```

```
        // Do something after the result executes.
    }
}
```

The kind of result being executed depends on the action. An action returning a view includes all razor processing as part of the ViewResult being executed. An API method might perform some serialization as part of the execution of the result. Learn more about action results.

Result filters are only executed when an action or action filter produces an action result. Result filters are not executed when:

- An authorization filter or resource filter short-circuits the pipeline.
- An exception filter handles an exception by producing an action result.

The Microsoft.AspNetCore.Mvc.Filters.IResultFilter.OnResultExecuting method can short-circuit execution of the action result and subsequent result filters by setting Microsoft.AspNetCore.Mvc.Filters.ResultExecutingContext.Cancel to `true`. Write to the response object when short-circuiting to avoid generating an empty response. Throwing an exception in `IResultFilter.OnResultExecuting`:

- Prevents execution of the action result and subsequent filters.
- Is treated as a failure instead of a successful result.

When the Microsoft.AspNetCore.Mvc.Filters.IResultFilter.OnResultExecuted method runs, the response has probably already been sent to the client. If the response has already been sent to the client, it cannot be changed.

`ResultExecutedContext.Canceled` is set to `true` if the action result execution was short-circuited by another filter.

`ResultExecutedContext.Exception` is set to a non-null value if the action result or a subsequent result filter threw an exception. Setting `Exception` to null effectively handles an exception and prevents the exception from being thrown again later in the pipeline. There is no reliable way to write data to a response when handling an exception in a result filter. If the headers have been flushed to the client when an action result throws an exception, there's no reliable mechanism to send a failure code.

For an IAsyncResultFilter, a call to `await next` on the ResultExecutionDelegate executes any subsequent result filters and the action result. To short-circuit, set ResultExecutingContext.Cancel to `true` and don't call the `ResultExecutionDelegate`:

```
C#
```

```
public class SampleAsyncResultFilter : IAsyncResultFilter
{
    public async Task OnResultExecutionAsync(
        ResultExecutingContext context, ResultExecutionDelegate next)
    {
        if (context.Result is not EmptyResult)
        {
            await next();
        }
        else
        {
            context.Cancel = true;
        }
    }
}
```

The framework provides an abstract `ResultFilterAttribute` that can be subclassed. The ResponseHeaderAttribute class shown previously is an example of a result filter attribute.

IAlwaysRunResultFilter and IAsyncAlwaysRunResultFilter

The IAlwaysRunResultFilter and IAsyncAlwaysRunResultFilter interfaces declare an IResultFilter implementation that runs for all action results. This includes action results produced by:

- Authorization filters and resource filters that short-circuit.
- Exception filters.

For example, the following filter always runs and sets an action result (ObjectResult) with a *422 Unprocessable Entity* status code when content negotiation fails:

C#

```
public class UnprocessableResultFilter : IAlwaysRunResultFilter
{
    public void OnResultExecuting(ResultExecutingContext context)
    {
        if (context.Result is StatusCodeResult statusCodeResult
            && statusCodeResult.StatusCode ==
StatusCodes.Status415UnsupportedMediaType)
        {
            context.Result = new ObjectResult("Unprocessable")
            {
                StatusCode = StatusCodes.Status422UnprocessableEntity
            };
        }
    }
```

```
    public void OnResultExecuted(ResultExecutedContext context) { }
}
```

IFilterFactory

IFilterFactory implements IFilterMetadata. Therefore, an `IFilterFactory` instance can be used as an `IFilterMetadata` instance anywhere in the filter pipeline. When the runtime prepares to invoke the filter, it attempts to cast it to an `IFilterFactory`. If that cast succeeds, the CreateInstance method is called to create the `IFilterMetadata` instance that is invoked. This provides a flexible design, since the precise filter pipeline doesn't need to be set explicitly when the app starts.

`IFilterFactory.IsReusable`:

- Is a hint by the factory that the filter instance created by the factory may be reused outside of the request scope it was created within.
- Should ***not*** be used with a filter that depends on services with a lifetime other than singleton.

The ASP.NET Core runtime doesn't guarantee:

- That a single instance of the filter will be created.
- The filter will not be re-requested from the DI container at some later point.

> ⚠ **Warning**
>
> Only configure **IFilterFactory.IsReusable** to return `true` if the source of the filters is unambiguous, the filters are stateless, and the filters are safe to use across multiple HTTP requests. For instance, don't return filters from DI that are registered as scoped or transient if `IFilterFactory.IsReusable` returns `true`.

`IFilterFactory` can be implemented using custom attribute implementations as another approach to creating filters:

C#

```
public class ResponseHeaderFilterFactory : Attribute, IFilterFactory
{
    public bool IsReusable => false;
```

```
    public IFilterMetadata CreateInstance(IServiceProvider serviceProvider)
=>
        new InternalResponseHeaderFilter();

    private class InternalResponseHeaderFilter : IActionFilter
    {
        public void OnActionExecuting(ActionExecutingContext context) =>
            context.HttpContext.Response.Headers.Add(
                nameof(OnActionExecuting),
nameof(InternalResponseHeaderFilter));

        public void OnActionExecuted(ActionExecutedContext context) { }
    }
```

The filter is applied in the following code:

C#

```
[ResponseHeaderFilterFactory]
public IActionResult Index() =>
    Content($"- {nameof(FilterFactoryController)}.{nameof(Index)}");
```

IFilterFactory implemented on an attribute

Filters that implement `IFilterFactory` are useful for filters that:

- Don't require passing parameters.
- Have constructor dependencies that need to be filled by DI.

TypeFilterAttribute implements IFilterFactory. `IFilterFactory` exposes the CreateInstance method for creating an IFilterMetadata instance. `CreateInstance` loads the specified type from the services container (DI).

C#

```
public class SampleActionTypeFilterAttribute : TypeFilterAttribute
{
    public SampleActionTypeFilterAttribute()
         : base(typeof(InternalSampleActionFilter)) { }

    private class InternalSampleActionFilter : IActionFilter
    {
        private readonly ILogger<InternalSampleActionFilter> _logger;

        public
InternalSampleActionFilter(ILogger<InternalSampleActionFilter> logger) =>
            _logger = logger;

        public void OnActionExecuting(ActionExecutingContext context)
```

```
        {
            _logger.LogInformation(
                $"- {nameof(InternalSampleActionFilter)}.
{nameof(OnActionExecuting)}");
        }

        public void OnActionExecuted(ActionExecutedContext context)
        {
            _logger.LogInformation(
                $"- {nameof(InternalSampleActionFilter)}.
{nameof(OnActionExecuted)}");
        }
    }
}
```

The following code shows three approaches to applying the filter:

C#

```
[SampleActionTypeFilter]
public IActionResult WithDirectAttribute() =>
    Content($"- {nameof(FilterFactoryController)}.
{nameof(WithDirectAttribute)}");

[TypeFilter<SampleActionTypeFilterAttribute>]
public IActionResult WithTypeFilterAttribute() =>
    Content($"- {nameof(FilterFactoryController)}.
{nameof(WithTypeFilterAttribute)}");

[ServiceFilter<SampleActionTypeFilterAttribute>]
public IActionResult WithServiceFilterAttribute() =>
    Content($"- {nameof(FilterFactoryController)}.
{nameof(WithServiceFilterAttribute)}");
```

In the preceding code, the first approach to applying the filter is preferred.

Use middleware in the filter pipeline

Resource filters work like middleware in that they surround the execution of everything that comes later in the pipeline. But filters differ from middleware in that they're part of the runtime, which means that they have access to context and constructs.

To use middleware as a filter, create a type with a `Configure` method that specifies the middleware to inject into the filter pipeline. The following example uses middleware to set a response header:

C#

```
public class FilterMiddlewarePipeline
{
    public void Configure(IApplicationBuilder app)
    {
        app.Use(async (context, next) =>
        {
            context.Response.Headers.Add("Pipeline", "Middleware");

            await next();
        });
    }
}
```

Use the MiddlewareFilterAttribute to run the middleware:

C#

```
[MiddlewareFilter<FilterMiddlewarePipeline>]
public class FilterMiddlewareController : Controller
{
    public IActionResult Index() =>
        Content($"- {nameof(FilterMiddlewareController)}.{nameof(Index)}");
}
```

Middleware filters run at the same stage of the filter pipeline as Resource filters, before model binding and after the rest of the pipeline.

Thread safety

When passing an *instance* of a filter into `Add`, instead of its `Type`, the filter is a singleton and is **not** thread-safe.

ASP.NET Core Razor SDK

Article • 04/10/2024

By Rick Anderson

Overview

The .NET 6.0 SDK includes the `Microsoft.NET.Sdk.Razor` MSBuild SDK (Razor SDK). The Razor SDK:

- Is required to build, package, and publish projects containing Razor files for ASP.NET Core MVC-based or Blazor projects.
- Includes a set of predefined properties, and items that allow customizing the compilation of Razor (`.cshtml` or `.razor`) files.

The Razor SDK includes `Content` items with `Include` attributes set to the `**\*.cshtml` and `**\*.razor` globbing patterns. Matching files are published.

Prerequisites

.NET 6.0 SDK

Use the Razor SDK

Most web apps aren't required to explicitly reference the Razor SDK.

To use the Razor SDK to build class libraries containing Razor views or Razor Pages, we recommend starting with the Razor class library (RCL) project template. An RCL that's used to build Blazor (`.razor`) files minimally requires a reference to the Microsoft.AspNetCore.Components package. An RCL that's used to build Razor views or pages (`.cshtml` files) minimally requires targeting `netcoreapp3.0` or later and has a `FrameworkReference` to the Microsoft.AspNetCore.App metapackage in its project file.

Properties

The following properties control the Razor's SDK behavior as part of a project build:

- `RazorCompileOnBuild`: When `true`, compiles and emits the Razor assembly as part of building the project. Defaults to `true`.

- `RazorCompileOnPublish`: When `true`, compiles and emits the Razor assembly as part of publishing the project. Defaults to `true`.
- `UseRazorSourceGenerator`: Defaults to `true`. When `true`:
  - Compiles using source generation.
  - Doesn't create `<app_name>.Views.dll`. Views are included in `<app_name>.dll`.
  - Supports .NET Hot Reload.

The properties and items in the following table are used to configure inputs and output to the Razor SDK.

Expand table

Items	Description
`RazorGenerate`	Item elements (`.cshtml` files) that are inputs to code generation.
`RazorComponent`	Item elements (`.razor` files) that are inputs to Razor component code generation.
`RazorCompile`	Item elements (`.cs` files) that are inputs to Razor compilation targets. Use this `ItemGroup` to specify additional files to be compiled into the Razor assembly.
`RazorEmbeddedResource`	Item elements added as embedded resources to the generated Razor assembly.

Expand table

Property	Description
`RazorOutputPath`	The Razor output directory.
`RazorCompileToolset`	Used to determine the toolset used to build the Razor assembly. Valid values are `Implicit`, `RazorSDK`, and `PrecompilationTool`.
EnableDefaultContentItems	Default is `true`. When `true`, includes *web.config*, `.json`, and `.cshtml` files as content in the project. When referenced via `Microsoft.NET.Sdk.Web`, files under *wwwroot* and config files are also included.
`EnableDefaultRazorGenerateItems`	When `true`, includes `.cshtml` files from `Content` items in `RazorGenerate` items.
`GenerateRazorTargetAssemblyInfo`	Not used in .NET 6 and later.

Property	Description
`EnableDefaultRazorTargetAssemblyInfoAttributes`	Not used in .NET 6 and later.
`CopyRazorGenerateFilesToPublishDirectory`	When `true`, copies `RazorGenerate` items (`.cshtml`) files to the publish directory. Typically, Razor files aren't required for a published app if they participate in compilation at build-time or publish-time. Defaults to `false`.
`PreserveCompilationReferences`	When `true`, copy reference assembly items to the publish directory. Typically, reference assemblies aren't required for a published app if Razor compilation occurs at build-time or publish-time. Set to `true` if your published app requires runtime compilation. For example, set the value to `true` if the app modifies `.cshtml` files at runtime or uses embedded views. Defaults to `false`.
`IncludeRazorContentInPack`	When `true`, all Razor content items (`.cshtml` files) are marked for inclusion in the generated NuGet package. Defaults to `false`.
`EmbedRazorGenerateSources`	When `true`, adds RazorGenerate (`.cshtml`) items as embedded files to the generated Razor assembly. Defaults to `false`.
`GenerateMvcApplicationPartsAssemblyAttributes`	Not used in .NET 6 and later.
`DefaultWebContentItemExcludes`	A globbing pattern for item elements that are to be excluded from the `Content` item group in projects targeting the Web or Razor SDK
`ExcludeConfigFilesFromBuildOutput`	When `true`, *.config* and `.json` files do not get copied to the build output directory.
`AddRazorSupportForMvc`	When `true`, configures the Razor SDK to add support for the MVC configuration that is required when building applications containing MVC views or Razor Pages. This property is implicitly set for .NET Core 3.0 or later projects targeting the Web SDK
`RazorLangVersion`	The version of the Razor Language to target.
`EmitCompilerGeneratedFiles`	When set to `true`, the generated source files are written to disk. Setting to `true` is useful

Property	Description
	when debugging the compiler. The default is `false`.

For more information on properties, see MSBuild properties.

Runtime compilation of Razor views

- By default, the Razor SDK doesn't publish reference assemblies that are required to perform runtime compilation. This results in compilation failures when the application model relies on runtime compilation—for example, the app uses embedded views or changes views after the app is published. Set `CopyRefAssembliesToPublishDirectory` to `true` to continue publishing reference assemblies. Both code generation and compilation are supported by a single call to the compiler. A single assembly is produced that contains the app types and the generated views.
- For a web app, ensure your app is targeting the `Microsoft.NET.Sdk.Web` SDK.

Razor language version

When targeting the `Microsoft.NET.Sdk.Web` SDK, the Razor language version is inferred from the app's target framework version. For projects targeting the `Microsoft.NET.Sdk.Razor` SDK or in the rare case that the app requires a different Razor language version than the inferred value, a version can be configured by setting the `<RazorLangVersion>` property in the app's project file:

XML

```
<PropertyGroup>
  <RazorLangVersion>{VERSION}</RazorLangVersion>
</PropertyGroup>
```

Razor's language version is tightly integrated with the version of the runtime that it was built for. Targeting a language version that isn't designed for the runtime is unsupported and likely produces build errors.

View components in ASP.NET Core

Article • 09/25/2023

By Rick Anderson

View components

View components are similar to partial views, but they're much more powerful. View components don't use model binding, they depend on the data passed when calling the view component. This article was written using controllers and views, but view components work with Razor Pages.

A view component:

- Renders a chunk rather than a whole response.
- Includes the same separation-of-concerns and testability benefits found between a controller and view.
- Can have parameters and business logic.
- Is typically invoked from a layout page.

View components are intended anywhere reusable rendering logic that's too complex for a partial view, such as:

- Dynamic navigation menus
- Tag cloud, where it queries the database
- Sign in panel
- Shopping cart
- Recently published articles
- Sidebar content on a blog
- A sign in panel that would be rendered on every page and show either the links to sign out or sign in, depending on the sign in state of the user

A view component consists of two parts:

- The class, typically derived from ViewComponent
- The result it returns, typically a view.

Like controllers, a view component can be a POCO, but most developers take advantage of the methods and properties available by deriving from ViewComponent.

When considering if view components meet an app's specifications, consider using Razor components instead. Razor components also combine markup with C# code to

produce reusable UI units. Razor components are designed for developer productivity when providing client-side UI logic and composition. For more information, see ASP.NET Core Razor components. For information on how to incorporate Razor components into an MVC or Razor Pages app, see Integrate ASP.NET Core Razor components into ASP.NET Core apps.

Create a view component

This section contains the high-level requirements to create a view component. Later in the article, we'll examine each step in detail and create a view component.

The view component class

A view component class can be created by any of the following:

- Deriving from ViewComponent
- Decorating a class with the [ViewComponent] attribute, or deriving from a class with the `[ViewComponent]` attribute
- Creating a class where the name ends with the suffix ViewComponent

Like controllers, view components must be public, non-nested, and non-abstract classes. The view component name is the class name with the `ViewComponent` suffix removed. It can also be explicitly specified using the Name property.

A view component class:

- Supports constructor dependency injection
- Doesn't take part in the controller lifecycle, therefore filters can't be used in a view component

To prevent a class that has a case-insensitive `ViewComponent` suffix from being treated as a view component, decorate the class with the [NonViewComponent] attribute:

C#

```
using Microsoft.AspNetCore.Mvc;

[NonViewComponent]
public class ReviewComponent
{
    public string Status(string name) => JobStatus.GetCurrentStatus(name);
}
```

View component methods

A view component defines its logic in an:

- `InvokeAsync` method that returns `Task<IViewComponentResult>`.
- `Invoke` synchronous method that returns an IViewComponentResult.

Parameters come directly from invocation of the view component, not from model binding. A view component never directly handles a request. Typically, a view component initializes a model and passes it to a view by calling the `View` method. In summary, view component methods:

- Define an `InvokeAsync` method that returns a `Task<IViewComponentResult>` or a synchronous `Invoke` method that returns an `IViewComponentResult`.
- Typically initializes a model and passes it to a view by calling the ViewComponent.View method.
- Parameters come from the calling method, not HTTP. There's no model binding.
- Aren't reachable directly as an HTTP endpoint. They're typically invoked in a view. A view component never handles a request.
- Are overloaded on the signature rather than any details from the current HTTP request.

View search path

The runtime searches for the view in the following paths:

- /Views/{Controller Name}/Components/{View Component Name}/{View Name}
- /Views/Shared/Components/{View Component Name}/{View Name}
- /Pages/Shared/Components/{View Component Name}/{View Name}
- /Areas/{Area Name}/Views/Shared/Components/{View Component Name}/{View Name}

The search path applies to projects using controllers + views and Razor Pages.

The default view name for a view component is `Default`, which means view files will typically be named `Default.cshtml`. A different view name can be specified when creating the view component result or when calling the `View` method.

We recommend naming the view file `Default.cshtml` and using the *Views/Shared/Components/{View Component Name}/{View Name}* path. The `PriorityList` view component used in this sample uses `Views/Shared/Components/PriorityList/Default.cshtml` for the view component view.

Customize the view search path

To customize the view search path, modify Razor's ViewLocationFormats collection. For example, to search for views within the path `/Components/{View Component Name}/{View Name}`, add a new item to the collection:

C#

```
using Microsoft.EntityFrameworkCore;
using ViewComponentSample.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllersWithViews()
    .AddRazorOptions(options =>
    {
        options.ViewLocationFormats.Add("/{0}.cshtml");
    });

builder.Services.AddDbContext<ToDoContext>(options =>
        options.UseInMemoryDatabase("db"));

var app = builder.Build();

// Remaining code removed for brevity.
```

In the preceding code, the placeholder `{0}` represents the path `Components/{View Component Name}/{View Name}`.

Invoke a view component

To use the view component, call the following inside a view:

CSHTML

```
@await Component.InvokeAsync("Name of view component",
                              {Anonymous Type Containing Parameters})
```

The parameters are passed to the `InvokeAsync` method. The `PriorityList` view component developed in the article is invoked from the `Views/ToDo/Index.cshtml` view file. In the following code, the `InvokeAsync` method is called with two parameters:

CSHTML

```
</table>
```

```
<div>
    Maximum Priority: @ViewData["maxPriority"] <br />
    Is Complete:  @ViewData["isDone"]
    @await Component.InvokeAsync("PriorityList",
                      new {
                          maxPriority =  ViewData["maxPriority"],
                          isDone = ViewData["isDone"]  }
                      )
</div>
```

Invoke a view component as a Tag Helper

A View Component can be invoked as a Tag Helper:

CSHTML

```
<div>
       Maxium Priority: @ViewData["maxPriority"] <br />
       Is Complete:  @ViewData["isDone"]
    @{
        int maxPriority = Convert.ToInt32(ViewData["maxPriority"]);
        bool isDone = Convert.ToBoolean(ViewData["isDone"]);
    }
    <vc:priority-list max-priority=maxPriority is-done=isDone>
    </vc:priority-list>
</div>
```

Pascal-cased class and method parameters for Tag Helpers are translated into their kebab case. The Tag Helper to invoke a view component uses the `<vc></vc>` element. The view component is specified as follows:

CSHTML

```
<vc:[view-component-name]
  parameter1="parameter1 value"
  parameter2="parameter2 value">
</vc:[view-component-name]>
```

To use a view component as a Tag Helper, register the assembly containing the view component using the `@addTagHelper` directive. If the view component is in an assembly called `MyWebApp`, add the following directive to the `_ViewImports.cshtml` file:

CSHTML

```
@addTagHelper *, MyWebApp
```

A view component can be registered as a Tag Helper to any file that references the view component. See Managing Tag Helper Scope for more information on how to register Tag Helpers.

The `InvokeAsync` method used in this tutorial:

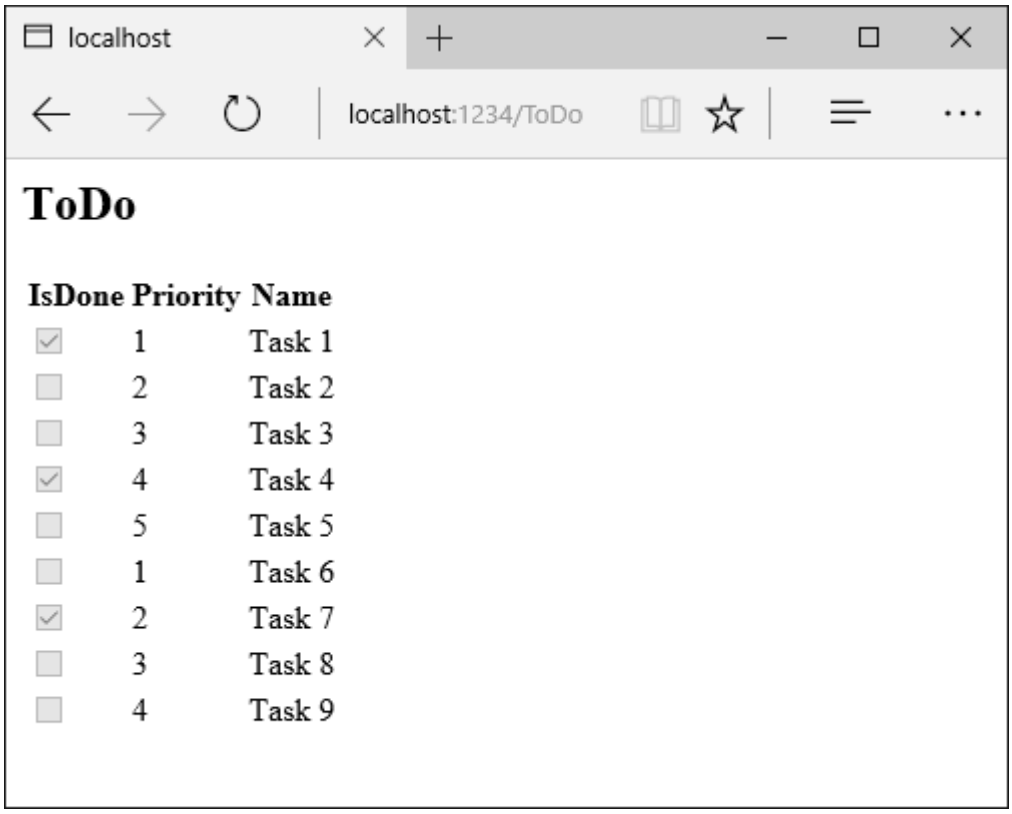
CSHTML

```
@await Component.InvokeAsync("PriorityList",
                  new {
                      maxPriority =  ViewData["maxPriority"],
                      isDone = ViewData["isDone"]  }
                  )
```

In the preceding markup, the `PriorityList` view component becomes `priority-list`. The parameters to the view component are passed as attributes in kebab case.

Invoke a view component directly from a controller

View components are typically invoked from a view, but they can be invoked directly from a controller method. While view components don't define endpoints like controllers, a controller action that returns the content of a `ViewComponentResult` can be implemented.



In the following example, the view component is called directly from the controller:

C#

```
public IActionResult IndexVC(int maxPriority = 2, bool isDone = false)
{
    return ViewComponent("PriorityList",
        new {
           maxPriority = maxPriority,
           isDone = isDone
        });
}
```

Create a basic view component

Download, build and test the starter code. It's a basic project with a `ToDo` controller that displays a list of *ToDo* items.

Update the controller to pass in priority and completion status

Update the `Index` method to use priority and completion status parameters:

C#

```
using Microsoft.AspNetCore.Mvc;
using ViewComponentSample.Models;

namespace ViewComponentSample.Controllers;
public class ToDoController : Controller
{
    private readonly ToDoContext _ToDoContext;

    public ToDoController(ToDoContext context)
    {
        _ToDoContext = context;
        _ToDoContext.Database.EnsureCreated();
    }

    public IActionResult Index(int maxPriority = 2, bool isDone = false)
    {
        var model = _ToDoContext!.ToDo!.ToList();
        ViewData["maxPriority"] = maxPriority;
        ViewData["isDone"] = isDone;
        return View(model);
    }
```

Add a ViewComponent class

Add a ViewComponent class to `ViewComponents/PriorityListViewComponent.cs`:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using ViewComponentSample.Models;

namespace ViewComponentSample.ViewComponents;

public class PriorityListViewComponent : ViewComponent
{
    private readonly ToDoContext db;

    public PriorityListViewComponent(ToDoContext context) => db = context;

    public async Task<IViewComponentResult> InvokeAsync(
                                            int maxPriority, bool isDone)
    {
        var items = await GetItemsAsync(maxPriority, isDone);
        return View(items);
    }

    private Task<List<TodoItem>> GetItemsAsync(int maxPriority, bool isDone)
    {
        return db!.ToDo!.Where(x => x.IsDone == isDone &&
                               x.Priority <= maxPriority).ToListAsync();
    }
}
```

Notes on the code:

- View component classes can be contained in **any** folder in the project.
- Because the class name PriorityList**ViewComponent** ends with the suffix **ViewComponent**, the runtime uses the string `PriorityList` when referencing the class component from a view.
- The [ViewComponent] attribute can change the name used to reference a view component. For example, the class could have been named `XYZ` with the following `[ViewComponent]` attribute:

  C#

  ```
  [ViewComponent(Name = "PriorityList")]
     public class XYZ : ViewComponent
  ```

- The `[ViewComponent]` attribute in the preceding code tells the view component selector to use:
  - The name `PriorityList` when looking for the views associated with the component
  - The string "PriorityList" when referencing the class component from a view.
- The component uses dependency injection to make the data context available.
- `InvokeAsync` exposes a method that can be called from a view, and it can take an arbitrary number of arguments.
- The `InvokeAsync` method returns the set of `ToDo` items that satisfy the `isDone` and `maxPriority` parameters.

Create the view component Razor view

- Create the *Views/Shared/Components* folder. This folder **must** be named *Components*.
- Create the *Views/Shared/Components/PriorityList* folder. This folder name must match the name of the view component class, or the name of the class minus the suffix. If the `ViewComponent` attribute is used, the class name would need to match the attribute designation.
- Create a `Views/Shared/Components/PriorityList/Default.cshtml` Razor view:

  CSHTML

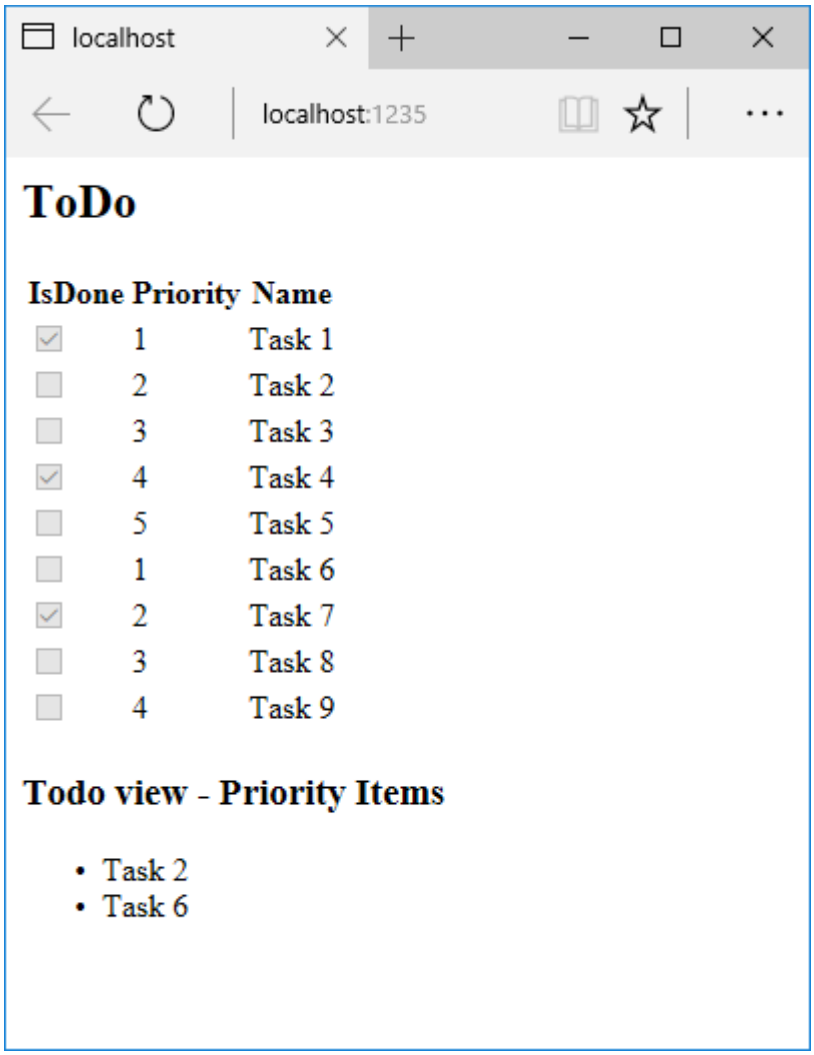
  ```
  @model IEnumerable<ViewComponentSample.Models.TodoItem>

  <h3>Priority Items</h3>
  <ul>
      @foreach (var todo in Model)
      {
          <li>@todo.Name</li>
      }
  </ul>
  ```

  The Razor view takes a list of `TodoItem` and displays them. If the view component `InvokeAsync` method doesn't pass the name of the view, *Default* is used for the view name by convention. To override the default styling for a specific controller, add a view to the controller-specific view folder (for example *Views/ToDo/Components/PriorityList/Default.cshtml*).

If the view component is controller-specific, it can be added to the controller-specific folder. For example, `Views/ToDo/Components/PriorityList/Default.cshtml` is controller-specific.

- Add a `div` containing a call to the priority list component to the bottom of the `Views/ToDo/index.cshtml` file:

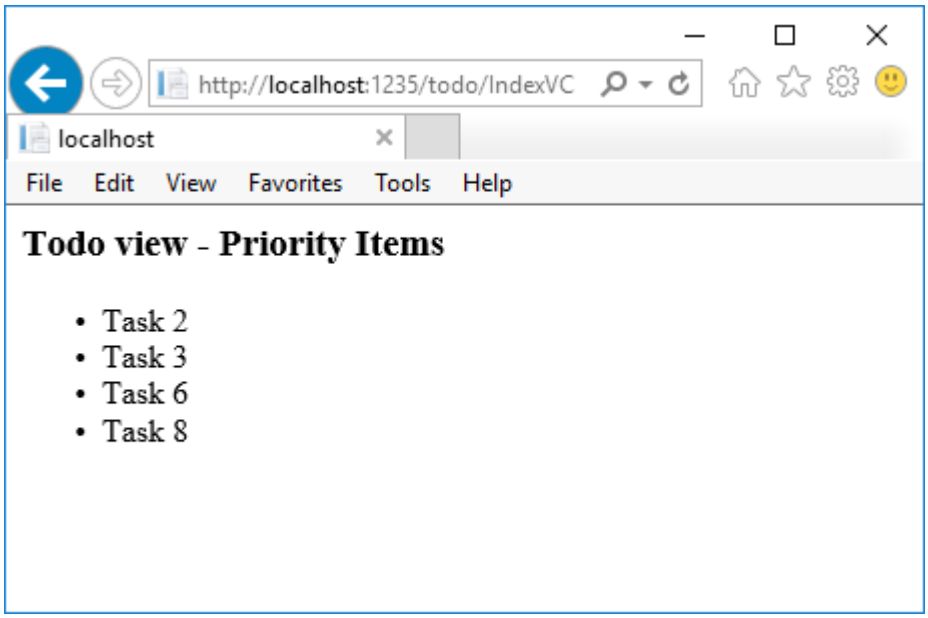


CSHTML

```
</table>

<div>
    Maximum Priority: @ViewData["maxPriority"] <br />
    Is Complete:  @ViewData["isDone"]
    @await Component.InvokeAsync("PriorityList",
                    new {
                        maxPriority =  ViewData["maxPriority"],
                        isDone = ViewData["isDone"]  }
                    )
</div>
```

The markup `@await Component.InvokeAsync` shows the syntax for calling view components. The first argument is the name of the component we want to invoke or call. Subsequent parameters are passed to the component. `InvokeAsync` can take an arbitrary number of arguments.



Test the app. The following image shows the ToDo list and the priority items:

The view component can be called directly from the controller:

C#

```
public IActionResult IndexVC(int maxPriority = 2, bool isDone = false)
{
    return ViewComponent("PriorityList",
        new {
           maxPriority = maxPriority,
           isDone = isDone
        });
}
```

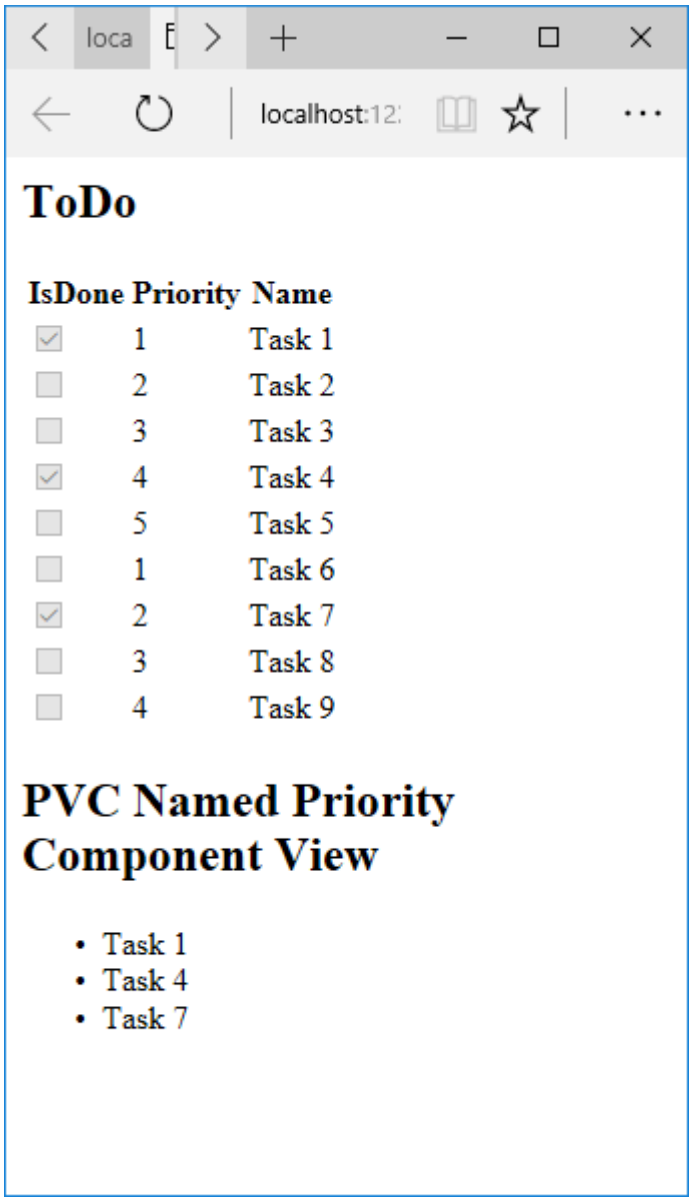
Specify a view component name

A complex view component might need to specify a non-default view under some conditions. The following code shows how to specify the "PVC" view from the `InvokeAsync` method. Update the `InvokeAsync` method in the `PriorityListViewComponent` class.

C#

```
public async Task<IViewComponentResult> InvokeAsync(
                                            int maxPriority, bool isDone)
{
    string MyView = "Default";
    // If asking for all completed tasks, render with the "PVC" view.
    if (maxPriority > 3 && isDone == true)
    {
        MyView = "PVC";
    }
    var items = await GetItemsAsync(maxPriority, isDone);
    return View(MyView, items);
}
```

Copy the `Views/Shared/Components/PriorityList/Default.cshtml` file to a view named `Views/Shared/Components/PriorityList/PVC.cshtml`. Add a heading to indicate the PVC view is being used.



CSHTML

```
@model IEnumerable<ViewComponentSample.Models.TodoItem>

<h2> PVC Named Priority Component View</h2>
<h4>@ViewBag.PriorityMessage</h4>
```

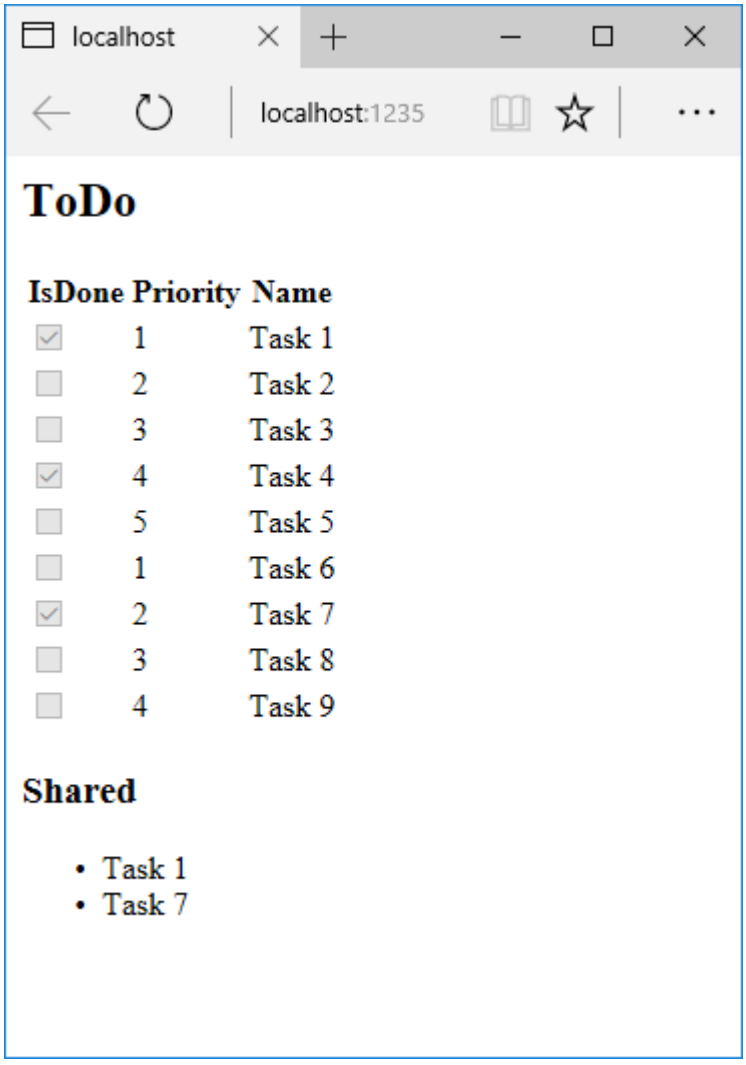
```
<ul>
    @foreach (var todo in Model)
    {
        <li>@todo.Name</li>
    }
</ul>
```

Run the app and verify PVC view.

If the PVC view isn't rendered, verify the view component with a priority of 4 or higher is called.

Examine the view path

- Change the priority parameter to three or less so the priority view isn't returned.
- Temporarily rename the `Views/ToDo/Components/PriorityList/Default.cshtml` to `1Default.cshtml`.



- Test the app, the following error occurs:

```txt
An unhandled exception occurred while processing the request.
InvalidOperationException: The view 'Components/PriorityList/Default'
wasn't found. The following locations were searched:
/Views/ToDo/Components/PriorityList/Default.cshtml
/Views/Shared/Components/PriorityList/Default.cshtml
```

- Copy `Views/ToDo/Components/PriorityList/1Default.cshtml` to `Views/Shared/Components/PriorityList/Default.cshtml`.

- Add some markup to the *Shared* ToDo view component view to indicate the view is from the *Shared* folder.

- Test the **Shared** component view.

Avoid hard-coded strings

For compile time safety, replace the hard-coded view component name with the class name. Update the *PriorityListViewComponent.cs* file to not use the "ViewComponent" suffix:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using ViewComponentSample.Models;

namespace ViewComponentSample.ViewComponents;

public class PriorityList : ViewComponent
{
    private readonly ToDoContext db;

    public PriorityList(ToDoContext context)
    {
        db = context;
    }

    public async Task<IViewComponentResult> InvokeAsync(
                                                int maxPriority, bool isDone)
    {
        var items = await GetItemsAsync(maxPriority, isDone);
        return View(items);
    }

    private Task<List<TodoItem>> GetItemsAsync(int maxPriority, bool isDone)
    {
        return db!.ToDo!.Where(x => x.IsDone == isDone &&
                               x.Priority <= maxPriority).ToListAsync();
    }
}
```

The view file:

CSHTML

```
</table>

<div>
    Testing nameof(PriorityList) <br />

    Maxium Priority: @ViewData["maxPriority"] <br />
    Is Complete:  @ViewData["isDone"]
    @await Component.InvokeAsync(nameof(PriorityList),
                        new {
                            maxPriority =  ViewData["maxPriority"],
                            isDone = ViewData["isDone"]  }
```

```
                    )
</div>
```

An overload of `Component.InvokeAsync` method that takes a CLR type uses the `typeof` operator:

CSHTML

```
</table>

<div>
    Testing typeof(PriorityList) <br />

    Maxium Priority: @ViewData["maxPriority"] <br />
    Is Complete:  @ViewData["isDone"]
    @await Component.InvokeAsync(typeof(PriorityList),
                    new {
                        maxPriority =  ViewData["maxPriority"],
                        isDone = ViewData["isDone"]  }
                    )
</div>
```

Perform synchronous work

The framework handles invoking a synchronous `Invoke` method if asynchronous work isn't required. The following method creates a synchronous `Invoke` view component:

C#

```
using Microsoft.AspNetCore.Mvc;
using ViewComponentSample.Models;

namespace ViewComponentSample.ViewComponents
{
    public class PriorityListSync : ViewComponent
    {
        private readonly ToDoContext db;

        public PriorityListSync(ToDoContext context)
        {
            db = context;
        }

        public IViewComponentResult Invoke(int maxPriority, bool isDone)
        {

            var x = db!.ToDo!.Where(x => x.IsDone == isDone &&
                                    x.Priority <= maxPriority).ToList();
            return View(x);
```

```
        }
    }
}
```

The view component's Razor file:

CSHTML

```
<div>
    Testing nameof(PriorityList) <br />

    Maxium Priority: @ViewData["maxPriority"] <br />
    Is Complete:  @ViewData["isDone"]
    @await Component.InvokeAsync(nameof(PriorityListSync),
                    new {
                        maxPriority =  ViewData["maxPriority"],
                        isDone = ViewData["isDone"]  }
                    )
</div>
```

The view component is invoked in a Razor file (for example, `Views/Home/Index.cshtml`) using one of the following approaches:

- IViewComponentHelper
- Tag Helper

To use the IViewComponentHelper approach, call `Component.InvokeAsync`:

CSHTML

```
@await Component.InvokeAsync(nameof(PriorityList),
                              new { maxPriority = 4, isDone = true })
```

To use the Tag Helper, register the assembly containing the View Component using the `@addTagHelper` directive (the view component is in an assembly called `MyWebApp`):

CSHTML

```
@addTagHelper *, MyWebApp
```

Use the view component Tag Helper in the Razor markup file:

CSHTML

```
<vc:priority-list max-priority="999" is-done="false">
</vc:priority-list>
```

The method signature of `PriorityList.Invoke` is synchronous, but Razor finds and calls the method with `Component.InvokeAsync` in the markup file.

Razor file compilation in ASP.NET Core

Article • 08/30/2024

Razor files with a `.cshtml` extension are compiled at both build and publish time using the Razor SDK. Runtime compilation may be optionally enabled by configuring the project.

> **Note**
>
> Runtime compilation:
>
> - Isn't supported for Razor components of Blazor apps.
> - Doesn't support global using directives.
> - Doesn't support implicit using directives.
> - Disables .NET Hot Reload.
> - Is recommended for development, not for production.

Razor compilation

Build-time and publish-time compilation of Razor files is enabled by default by the Razor SDK. When enabled, runtime compilation complements build-time compilation, allowing Razor files to be updated if they're edited while the app is running.

Updating Razor views and Razor Pages during development while the app is running is also supported using .NET Hot Reload.

> **Note**
>
> When enabled, runtime compilation disables .NET Hot Reload. We recommend using Hot Reload instead of Razor runtime compilation during development.

Enable runtime compilation for all environments

To enable runtime compilation for all environments:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.

2. Call AddRazorRuntimeCompilation in `Program.cs`:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddRazorPages()
    .AddRazorRuntimeCompilation();
```

Enable runtime compilation conditionally

Runtime compilation can be enabled conditionally, which ensures that the published output:

- Uses compiled views.
- Doesn't enable file watchers in production.

To enable runtime compilation only for the Development environment:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.
2. Call AddRazorRuntimeCompilation in `Program.cs` when the current environment is set to Development:

```
C#

var builder = WebApplication.CreateBuilder(args);

var mvcBuilder = builder.Services.AddRazorPages();

if (builder.Environment.IsDevelopment())
{
    mvcBuilder.AddRazorRuntimeCompilation();
}
```

Runtime compilation can also be enabled with a hosting startup assembly. To enable runtime compilation in the Development environment for specific launch profiles:

1. Install the Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation NuGet package.
2. Modify the launch profile's `environmentVariables` section in `launchSettings.json`:
    - Verify that `ASPNETCORE_ENVIRONMENT` is set to `"Development"`.

- Set `ASPNETCORE_HOSTINGSTARTUPASSEMBLIES` to `"Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation"`. For example, the following `launchSettings.json` enables runtime compilation for the `ViewCompilationSample` and `IIS Express` launch profiles:

JSON

```
{
  "iisSettings": {
    "windowsAuthentication": false,
    "anonymousAuthentication": true,
    "iisExpress": {
      "applicationUrl": "http://localhost:7098",
      "sslPort": 44332
    }
  },
  "profiles": {
    "ViewCompilationSample": {
      "commandName": "Project",
      "dotnetRunMessages": true,
      "launchBrowser": true,
      "applicationUrl":
"https://localhost:7173;http://localhost:5251",
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development",
        "ASPNETCORE_HOSTINGSTARTUPASSEMBLIES":
"Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation"
      }
    },
    "IIS Express": {
      "commandName": "IISExpress",
      "launchBrowser": true,
      "environmentVariables": {
        "ASPNETCORE_ENVIRONMENT": "Development",
        "ASPNETCORE_HOSTINGSTARTUPASSEMBLIES":
"Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation"
      }
    }
  }
}
```

With this approach, no code changes are needed in `Program.cs`. At runtime, ASP.NET Core searches for an assembly-level HostingStartup attribute in `Microsoft.AspNetCore.Mvc.Razor.RuntimeCompilation`. The `HostingStartup` attribute specifies the app startup code to execute and that startup code enables runtime compilation.

Enable runtime compilation for a Razor class library

Consider a scenario in which a Razor Pages project references a Razor class library (RCL) named *MyClassLib*. The RCL contains a `_Layout.cshtml` file consumed by MVC and Razor Pages projects. To enable runtime compilation for the `_Layout.cshtml` file in that RCL, make the following changes in the Razor Pages project:

1. Enable runtime compilation with the instructions at Enable runtime compilation conditionally.

2. Configure MvcRazorRuntimeCompilationOptions in `Program.cs`:

   C#

   ```
   var builder = WebApplication.CreateBuilder(args);

   builder.Services.AddRazorPages();

   builder.Services.Configure<MvcRazorRuntimeCompilationOptions>(options
   =>
   {
       var libraryPath = Path.GetFullPath(
           Path.Combine(builder.Environment.ContentRootPath, "..",
   "MyClassLib"));

       options.FileProviders.Add(new PhysicalFileProvider(libraryPath));
   });
   ```

   The preceding code builds an absolute path to the *MyClassLib* RCL. The PhysicalFileProvider API is used to locate directories and files at that absolute path. Finally, the `PhysicalFileProvider` instance is added to a file providers collection, which allows access to the RCL's `.cshtml` files.

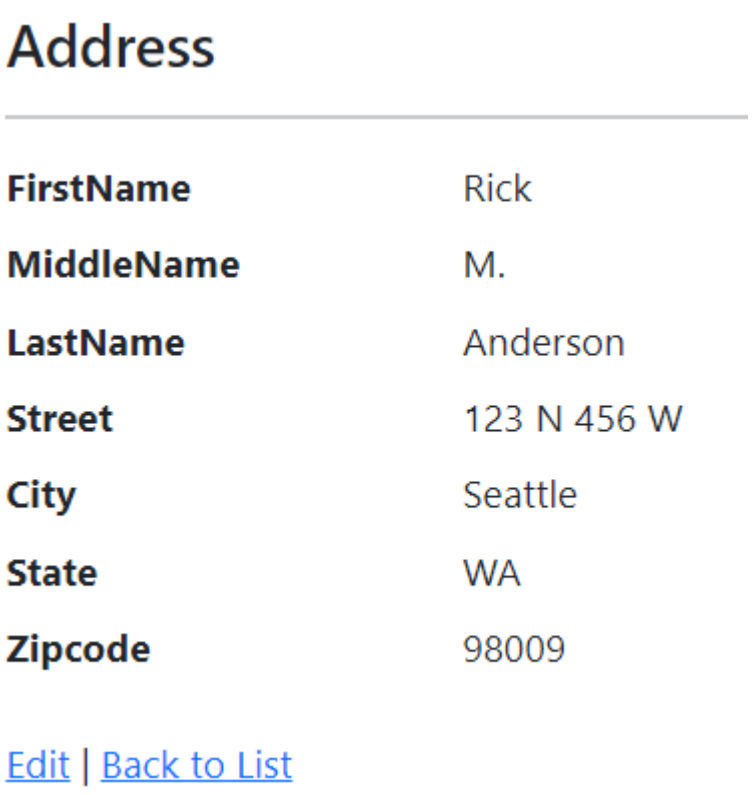
Display and Editor templates in ASP.NET Core

Article • 06/15/2023



By Alexander Wicht

Display and Editor templates specify the user interface layout of custom types. Consider the following `Address` model:

C#

```
public class Address
{
    public int Id { get; set; }
    public string FirstName { get; set; } = null!;
    public string MiddleName { get; set; } = null!;
    public string LastName { get; set; } = null!;
    public string Street { get; set; } = null!;
    public string City { get; set; } = null!;
    public string State { get; set; } = null!;
    public string Zipcode { get; set; } = null!;
}
```

A project that scaffolds the `Address` model displays the `Address` in the following form:

A web site could use a Display Template to show the `Address` in standard format:

Display and Editor templates can also reduce code duplication and maintenance costs. Consider a web site that displays the `Address` model on 20 different pages. If the `Address` model changes, the 20 pages will all need to be updated. If a Display Template is used for the `Address` model, only the Display Template needs to be updated. For example, the `Address` model might be updated to include the country or region.

Tag Helpers provide an alternative way that enables server-side code to participate in creating and rendering HTML elements in Razor files. For more information, see Tag Helpers compared to HTML Helpers.

Display templates

`DisplayTemplates` customize the display of model fields or create a layer of abstraction between the model values and their display.

A `DisplayTemplate` is a Razor file placed in the `DisplayTemplates` folder:

- For Razor Pages apps, in the `Pages/Shared/DisplayTemplates` folder.
- For MVC apps, in the `Views/Shared/DisplayTemplates` folder or the `Views/ControllerName/DisplayTemplates` folder. Display templates in the `Views/Shared/DisplayTemplates` are used by all controllers in the app. Display templates in the `Views/ControllerName/DisplayTemplates` folder are resolved only by the `ControllerName` controller.

By convention, the `DisplayTemplate` file is named after the type to be displayed. The `Address.cshtml` template used in this sample:

CSHTML

```
@model Address

<dl>
    <dd>@Model.FirstName @Model.MiddleName @Model.LastName</dd>
    <dd>@Model.Street</dd>
    <dd>@Model.City @Model.State @Model.Zipcode</dd>
</dl>
```

The view engine automatically looks for a file in the `DisplayTemplates` folder that matches the name of the type. If it doesn't find a matching template, it falls back to the built in templates.

The following code shows the Details view of the scaffolded project:

CSHTML

```
@page
@model WebAddress.Pages.Adr.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Address</h4>
    <hr />
    <dl class="row">
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Address.FirstName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Address.FirstName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Address.MiddleName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Address.MiddleName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Address.LastName)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Address.LastName)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Address.Street)
        </dt>
```

```
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Address.Street)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Address.City)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Address.City)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Address.State)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Address.State)
        </dd>
        <dt class="col-sm-2">
            @Html.DisplayNameFor(model => model.Address.Zipcode)
        </dt>
        <dd class="col-sm-10">
            @Html.DisplayFor(model => model.Address.Zipcode)
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Address?.Id">Edit</a> |
    <a asp-page="./Index">Back to List</a>
</div>
```

The following code shows the Details view using the Address Display Template:

CSHTML

```
@page
@model WebAddress.Pages.Adr2.DetailsModel

@{
    ViewData["Title"] = "Details";
}

<h1>Details</h1>

<div>
    <h4>Address DM</h4>
    <hr />
    <dl class="row">
        <dd class="col-sm-10">
           @Html.DisplayFor(model => model.Address)
        </dd>
    </dl>
</div>
<div>
    <a asp-page="./Edit" asp-route-id="@Model.Address?.Id">Edit</a> |
```

```
    <a asp-page="./Index">Back to List</a>
</div>
```

To reference a template whose name doesn't match the type name, use the `templateName` parameter in the DisplayFor method. For example, the following markup displays the `Address` model with the `AddressShort` template:

CSHTML

```
@page
@model WebAddress.Pages.Adr2.DetailsCCModel

@{
    ViewData["Title"] = "Details Short";
}

<h1>Details Short</h1>

<div>
    <h4>Address Short</h4>
    <hr />
    <dl class="row">
        <dd class="col-sm-10">
           @Html.DisplayFor(model => model.Address,"AddressShort")
        </dd>
    </dl>
</div>
```

Use one of the available DisplayFor overloads that expose the `additionalViewData` parameter to pass additional view data that is merged into the View Data Dictionary instance created for the template.

Editor templates

Editor templates are used in form controls when the model is edited or updated.

An `EditorTemplate` is a Razor file placed in the `EditorTemplates` folder:

- For Razor Pages apps, in the `Pages/Shared/EditorTemplates` folder.
- For MVC apps, in the `Views/Shared/EditorTemplates` folder or the `Views/ControllerName/EditorTemplates` folder.

The following markup shows the `Pages/Shared/EditorTemplates/Address.cshtml` used in the sample:

CSHTML

```
@model Address

<dl>
    <dd>    Name:
        <input asp-for="FirstName" /> <input asp-for="MiddleName" /> <input
asp-for="LastName" />
    </dd>
        <dd>    Street:
        <input asp-for="Street" />
    </dd>

        <dd>    city/state/zip:
        <input asp-for="City" /> <input asp-for="State" /> <input asp-
for="Zipcode" />
    </dd>

</dl>
```

The following markup shows the *Edit.cshtml* page which uses the `Pages/Shared/EditorTemplates/Address.cshtml` template:

CSHTML

```
@page
@model WebAddress.Pages.Adr.EditModel

@{
    ViewData["Title"] = "Edit";
}

<h1>Edit</h1>

<h4>Address</h4>
<hr />
<div class="row">
    <div class="col-md-4">
        <form method="post">
            <div asp-validation-summary="ModelOnly" class="text-danger">
</div>
            <input type="hidden" asp-for="Address.Id" />
             @Html.EditorFor(model => model.Address)
            <div class="form-group">
                <input type="submit" value="Save" class="btn btn-primary" />
            </div>
        </form>
    </div>
</div>

<div>
    <a asp-page="./Index">Back to List</a>
</div>
```

```
@section Scripts {
    @{await Html.RenderPartialAsync("_ValidationScriptsPartial");}
}
```

Upload files in ASP.NET Core

Article • 09/27/2024

By Rutger Storm

ASP.NET Core supports uploading one or more files using buffered model binding for smaller files and unbuffered streaming for larger files.

View or download sample code (how to download)

Security considerations

Use caution when providing users with the ability to upload files to a server. Cyberattackers may attempt to:

- Execute denial of service attacks.
- Upload viruses or malware.
- Compromise networks and servers in other ways.

Security steps that reduce the likelihood of a successful attack are:

- Upload files to a dedicated file upload area, preferably to a non-system drive. A dedicated location makes it easier to impose security restrictions on uploaded files. Disable execute permissions on the file upload location.†
- Do **not** persist uploaded files in the same directory tree as the app.†
- Use a safe file name determined by the app. Don't use a file name provided by the user or the untrusted file name of the uploaded file.† HTML encode the untrusted file name when displaying it. For example, logging the file name or displaying in UI (Razor automatically HTML encodes output).
- Allow only approved file extensions for the app's design specification.†
- Verify that client-side checks are performed on the server.† Client-side checks are easy to circumvent.
- Check the size of an uploaded file. Set a maximum size limit to prevent large uploads.†
- When files shouldn't be overwritten by an uploaded file with the same name, check the file name against the database or physical storage before uploading the file.
- **Run a virus/malware scanner on uploaded content before the file is stored.**

†The sample app demonstrates an approach that meets the criteria.

> ⚠ **Warning**

Uploading malicious code to a system is frequently the first step to executing code that can:

- Completely gain control of a system.
- Overload a system with the result that the system crashes.
- Compromise user or system data.
- Apply graffiti to a public UI.

For information on reducing vulnerabilities when accepting files from users, see the following resources:

- Unrestricted File Upload
- Azure Security: Ensure appropriate controls are in place when accepting files from users

For more information on implementing security measures, including examples from the sample app, see the Validation section.

Storage scenarios

Common storage options for files include:

- Database
  - For small file uploads, a database is often faster than physical storage (file system or network share) options.
  - A database is often more convenient than physical storage options because retrieval of a database record for user data can concurrently supply the file content (for example, an avatar image).
  - A database is potentially less expensive than using a cloud data storage service.
- Physical storage (file system or network share)
  - For large file uploads:
    - Database limits may restrict the size of the upload.
    - Physical storage is often less economical than storage in a database.
  - Physical storage is potentially less expensive than using a cloud data storage service.
  - The app's process must have read and write permissions to the storage location. **Never grant execute permission.**
- Cloud data storage service, for example, Azure Blob Storage.

- Services usually offer improved scalability and resiliency over on-premises solutions that are usually subject to single points of failure.
- Services are potentially lower cost in large storage infrastructure scenarios.

For more information, see Quickstart: Use .NET to create a blob in object storage.

Small and large files

The definition of small and large files depend on the computing resources available. Apps should benchmark the storage approach used to ensure it can handle the expected sizes. Benchmark memory, CPU, disk, and database performance.

While specific boundaries can't be provided on what is small versus large for your deployment, here are some of ASP.NET Core's related defaults for FormOptions (API documentation):

- By default, HttpRequest.Form doesn't buffer the entire request body (BufferBody), but it does buffer any multipart form files included.
- MultipartBodyLengthLimit is the maximum size for buffered form files (default: 128 MB).
- MemoryBufferThreshold indicates the buffering threshold in memory before transitioning to a buffer file on disk (default: 64 KB). `MemoryBufferThreshold` acts as a boundary between small and large files, which is raised or lowered depending on the apps resources and scenarios.

For more information on FormOptions, see the FormOptions class in the ASP.NET Core reference source.

> **Note**
>
> Documentation links to .NET reference source usually load the repository's default branch, which represents the current development for the next release of .NET. To select a tag for a specific release, use the **Switch branches or tags** dropdown list. For more information, see How to select a version tag of ASP.NET Core source code (dotnet/AspNetCore.Docs #26205).

File upload scenarios

Two general approaches for uploading files are buffering and streaming.

Buffering

The entire file is read into an IFormFile. `IFormFile` is a C# representation of the file used to process or save the file.

The disk and memory used by file uploads depend on the number and size of concurrent file uploads. If an app attempts to buffer too many uploads, the site crashes when it runs out of memory or disk space. If the size or frequency of file uploads is exhausting app resources, use streaming.

Any single buffered file exceeding 64 KB is moved from memory to a temp file on disk.

Temporary files for larger requests are written to the location named in the `ASPNETCORE_TEMP` environment variable. If `ASPNETCORE_TEMP` is not defined, the files are written to the current user's temporary folder.

Buffering small files is covered in the following sections of this topic:

- Physical storage
- Database

Streaming

The file is received from a multipart request and directly processed or saved by the app. Streaming doesn't improve performance significantly. Streaming reduces the demands for memory or disk space when uploading files.

Streaming large files is covered in the Upload large files with streaming section.

Upload small files with buffered model binding to physical storage

To upload small files, use a multipart form or construct a POST request using JavaScript.

The following example demonstrates the use of a Razor Pages form to upload a single file (`Pages/BufferedSingleFileUploadPhysical.cshtml` in the sample app):

CSHTML

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file" />
            <span asp-validation-for="FileUpload.FormFile"></span>
        </dd>
```

```
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit"
value="Upload" />
</form>
```

The following example is analogous to the prior example except that:

- JavaScript's (Fetch API) is used to submit the form's data.
- There's no validation.

CSHTML

```
<form action="BufferedSingleFileUploadPhysical/?handler=Upload"
      enctype="multipart/form-data" onsubmit="AJAXSubmit(this);return
false;"
      method="post">
    <dl>
        <dt>
            <label for="FileUpload_FormFile">File</label>
        </dt>
        <dd>
            <input id="FileUpload_FormFile" type="file"
                name="FileUpload.FormFile" />
        </dd>
    </dl>

    <input class="btn" type="submit" value="Upload" />

    <div style="margin-top:15px">
        <output name="result"></output>
    </div>
</form>

<script>
  async function AJAXSubmit (oFormElement) {
    var resultElement = oFormElement.elements.namedItem("result");
    const formData = new FormData(oFormElement);

    try {
    const response = await fetch(oFormElement.action, {
      method: 'POST',
      body: formData
    });

    if (response.ok) {
      window.location.href = '/';
    }

    resultElement.value = 'Result: ' + response.status + ' ' +
      response.statusText;
    } catch (error) {
      console.error('Error:', error);
    }
```

```
  }
</script>
```

To perform the form POST in JavaScript for clients that don't support the Fetch API, use one of the following approaches:

- Use a Fetch Polyfill (for example, window.fetch polyfill (github/fetch)).
- Use `XMLHttpRequest`. For example:

JavaScript

```
<script>
  "use strict";

  function AJAXSubmit (oFormElement) {
    var oReq = new XMLHttpRequest();
    oReq.onload = function(e) {
    oFormElement.elements.namedItem("result").value =
      'Result: ' + this.status + ' ' + this.statusText;
    };
    oReq.open("post", oFormElement.action);
    oReq.send(new FormData(oFormElement));
  }
</script>
```

In order to support file uploads, HTML forms must specify an encoding type (`enctype`) of `multipart/form-data`.

For a `files` input element to support uploading multiple files provide the `multiple` attribute on the `<input>` element:

CSHTML

```
<input asp-for="FileUpload.FormFiles" type="file" multiple />
```

The individual files uploaded to the server can be accessed through Model Binding using IFormFile. The sample app demonstrates multiple buffered file uploads for database and physical storage scenarios.

> ⚠ **Warning**
>
> Do **not** use the `FileName` property of **IFormFile** other than for display and logging. When displaying or logging, HTML encode the file name. A cyberattacker can

provide a malicious filename, including full paths or relative paths. Applications should:

- Remove the path from the user-supplied filename.
- Save the HTML-encoded, path-removed filename for UI or logging.
- Generate a new random filename for storage.

The following code removes the path from the file name:

```
C#
string untrustedFileName = Path.GetFileName(pathName);
```

The examples provided thus far don't take into account security considerations. Additional information is provided by the following sections and the sample app:

- Security considerations
- Validation

When uploading files using model binding and IFormFile, the action method can accept:

- A single IFormFile.
- Any of the following collections that represent several files:
  - IFormFileCollection
  - IEnumerable<IFormFile>
  - List<IFormFile>

> **Note**
>
> Binding matches form files by name. For example, the HTML `name` value in `<input type="file" name="formFile">` must match the C# parameter/property bound (`FormFile`). For more information, see the Match name attribute value to parameter name of POST method section.

The following example:

- Loops through one or more uploaded files.
- Uses Path.GetTempFileName to return a full path for a file, including the file name.
- Saves the files to the local file system using a file name generated by the app.
- Returns the total number and size of files uploaded.

```
C#
```

```
public async Task<IActionResult> OnPostUploadAsync(List<IFormFile> files)
{
    long size = files.Sum(f => f.Length);

    foreach (var formFile in files)
    {
        if (formFile.Length > 0)
        {
            var filePath = Path.GetTempFileName();

            using (var stream = System.IO.File.Create(filePath))
            {
                await formFile.CopyToAsync(stream);
            }
        }
    }

    // Process uploaded files
    // Don't rely on or trust the FileName property without validation.

    return Ok(new { count = files.Count, size });
}
```

Use `Path.GetRandomFileName` to generate a file name without a path. In the following example, the path is obtained from configuration:

C#

```
foreach (var formFile in files)
{
    if (formFile.Length > 0)
    {
        var filePath = Path.Combine(_config["StoredFilesPath"],
            Path.GetRandomFileName());

        using (var stream = System.IO.File.Create(filePath))
        {
            await formFile.CopyToAsync(stream);
        }
    }
}
```

The path passed to the FileStream *must* include the file name. If the file name isn't provided, an UnauthorizedAccessException is thrown at runtime.

Files uploaded using the IFormFile technique are buffered in memory or on disk on the server before processing. Inside the action method, the IFormFile contents are accessible as a Stream. In addition to the local file system, files can be saved to a network share or to a file storage service, such as Azure Blob storage.

For another example that loops over multiple files for upload and uses safe file names, see `Pages/BufferedMultipleFileUploadPhysical.cshtml.cs` in the sample app.

> ⚠ **Warning**
>
> Path.GetTempFileName throws an IOException if more than 65,535 files are created without deleting previous temporary files. The limit of 65,535 files is a per-server limit. For more information on this limit on Windows OS, see the remarks in the following topics:
>
> - GetTempFileNameA function
> - GetTempFileName

Upload small files with buffered model binding to a database

To store binary file data in a database using Entity Framework, define a Byte array property on the entity:

C#

```
public class AppFile
{
    public int Id { get; set; }
    public byte[] Content { get; set; }
}
```

Specify a page model property for the class that includes an IFormFile:

C#

```
public class BufferedSingleFileUploadDbModel : PageModel
{
    ...

    [BindProperty]
    public BufferedSingleFileUploadDb FileUpload { get; set; }

    ...
}

public class BufferedSingleFileUploadDb
{
    [Required]
    [Display(Name="File")]
```

```
    public IFormFile FormFile { get; set; }
}
```

> ⓘ Note
>
> IFormFile can be used directly as an action method parameter or as a bound model property. The prior example uses a bound model property.

The `FileUpload` is used in the Razor Pages form:

CSHTML

```
<form enctype="multipart/form-data" method="post">
    <dl>
        <dt>
            <label asp-for="FileUpload.FormFile"></label>
        </dt>
        <dd>
            <input asp-for="FileUpload.FormFile" type="file">
        </dd>
    </dl>
    <input asp-page-handler="Upload" class="btn" type="submit"
value="Upload">
</form>
```

When the form is POSTed to the server, copy the IFormFile to a stream and save it as a byte array in the database. In the following example, `_dbContext` stores the app's database context:

C#

```
public async Task<IActionResult> OnPostUploadAsync()
{
    using (var memoryStream = new MemoryStream())
    {
        await FileUpload.FormFile.CopyToAsync(memoryStream);

        // Upload the file if less than 2 MB
        if (memoryStream.Length < 2097152)
        {
            var file = new AppFile()
            {
                Content = memoryStream.ToArray()
            };

            _dbContext.File.Add(file);

            await _dbContext.SaveChangesAsync();
```

```
        }
        else
        {
            ModelState.AddModelError("File", "The file is too large.");
        }
    }

    return Page();
}
```

The preceding example is similar to a scenario demonstrated in the sample app:

- `Pages/BufferedSingleFileUploadDb.cshtml`
- `Pages/BufferedSingleFileUploadDb.cshtml.cs`

> ⚠ **Warning**
>
> Use caution when storing binary data in relational databases, as it can adversely impact performance.
>
> Don't rely on or trust the `FileName` property of **IFormFile** without validation. The `FileName` property should only be used for display purposes and only after HTML encoding.
>
> The examples provided don't take into account security considerations. Additional information is provided by the following sections and the sample app:
>
> - Security considerations
> - Validation

Upload large files with streaming

The 3.1 example demonstrates how to use JavaScript to stream a file to a controller action. The file's antiforgery token is generated using a custom filter attribute and passed to the client HTTP headers instead of in the request body. Because the action method processes the uploaded data directly, form model binding is disabled by another custom filter. Within the action, the form's contents are read using a `MultipartReader`, which reads each individual `MultipartSection`, processing the file or storing the contents as appropriate. After the multipart sections are read, the action performs its own model binding.

The initial page response loads the form and saves an antiforgery token in a cookie (via the `GenerateAntiforgeryTokenCookieAttribute` attribute). The attribute uses ASP.NET

Core's built-in antiforgery support to set a cookie with a request token:

C#

```
public class GenerateAntiforgeryTokenCookieAttribute : ResultFilterAttribute
{
    public override void OnResultExecuting(ResultExecutingContext context)
    {
        var antiforgery =
context.HttpContext.RequestServices.GetService<IAntiforgery>();

        // Send the request token as a JavaScript-readable cookie
        var tokens = antiforgery.GetAndStoreTokens(context.HttpContext);

        context.HttpContext.Response.Cookies.Append(
            "RequestVerificationToken",
            tokens.RequestToken,
            new CookieOptions() { HttpOnly = false });
    }

    public override void OnResultExecuted(ResultExecutedContext context)
    {
    }
}
```

The `DisableFormValueModelBindingAttribute` is used to disable model binding:

C#

```
[AttributeUsage(AttributeTargets.Class | AttributeTargets.Method)]
public class DisableFormValueModelBindingAttribute : Attribute,
IResourceFilter
{
    public void OnResourceExecuting(ResourceExecutingContext context)
    {
        var factories = context.ValueProviderFactories;
        factories.RemoveType<FormValueProviderFactory>();
        factories.RemoveType<FormFileValueProviderFactory>();
        factories.RemoveType<JQueryFormValueProviderFactory>();
    }

    public void OnResourceExecuted(ResourceExecutedContext context)
    {
    }
}
```

In the sample app, `GenerateAntiforgeryTokenCookieAttribute` and `DisableFormValueModelBindingAttribute` are applied as filters to the page application models of `/StreamedSingleFileUploadDb` and `/StreamedSingleFileUploadPhysical` in `Startup.ConfigureServices` using Razor Pages conventions:

C#

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/StreamedSingleFileUploadDb",
            model =>
            {
                model.Filters.Add(
                    new GenerateAntiforgeryTokenCookieAttribute());
                model.Filters.Add(
                    new DisableFormValueModelBindingAttribute());
            });
    options.Conventions

.AddPageApplicationModelConvention("/StreamedSingleFileUploadPhysical",
            model =>
            {
                model.Filters.Add(
                    new GenerateAntiforgeryTokenCookieAttribute());
                model.Filters.Add(
                    new DisableFormValueModelBindingAttribute());
            });
});
```

Since model binding doesn't read the form, parameters that are bound from the form don't bind (query, route, and header continue to work). The action method works directly with the `Request` property. A `MultipartReader` is used to read each section. Key/value data is stored in a `KeyValueAccumulator`. After the multipart sections are read, the contents of the `KeyValueAccumulator` are used to bind the form data to a model type.

The complete `StreamingController.UploadDatabase` method for streaming to a database with EF Core:

C#

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadDatabase()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
        // Log error

        return BadRequest(ModelState);
    }
```

```
    // Accumulate the form data key-value pairs in the request
(formAccumulator).
    var formAccumulator = new KeyValueAccumulator();
    var trustedFileNameForDisplay = string.Empty;
    var untrustedFileNameForStorage = string.Empty;
    var streamedFileContent = Array.Empty<byte>();

    var boundary = MultipartRequestHelper.GetBoundary(
        MediaTypeHeaderValue.Parse(Request.ContentType),
        _defaultFormOptions.MultipartBoundaryLengthLimit);
    var reader = new MultipartReader(boundary, HttpContext.Request.Body);

    var section = await reader.ReadNextSectionAsync();

    while (section != null)
    {
        var hasContentDispositionHeader =
            ContentDispositionHeaderValue.TryParse(
                section.ContentDisposition, out var contentDisposition);

        if (hasContentDispositionHeader)
        {
            if (MultipartRequestHelper
                .HasFileContentDisposition(contentDisposition))
            {
                untrustedFileNameForStorage =
contentDisposition.FileName.Value;
                // Don't trust the file name sent by the client. To display
                // the file name, HTML-encode the value.
                trustedFileNameForDisplay = WebUtility.HtmlEncode(
                        contentDisposition.FileName.Value);

                streamedFileContent =
                    await FileHelpers.ProcessStreamedFile(section,
contentDisposition,
                        ModelState, _permittedExtensions, _fileSizeLimit);

                if (!ModelState.IsValid)
                {
                    return BadRequest(ModelState);
                }
            }
            else if (MultipartRequestHelper
                .HasFormDataContentDisposition(contentDisposition))
            {
                // Don't limit the key name length because the
                // multipart headers length limit is already in effect.
                var key = HeaderUtilities
                    .RemoveQuotes(contentDisposition.Name).Value;
                var encoding = GetEncoding(section);

                if (encoding == null)
                {
                    ModelState.AddModelError("File",
```

```
                        $"The request couldn't be processed (Error 2).");
                    // Log error

                    return BadRequest(ModelState);
                }

                using (var streamReader = new StreamReader(
                    section.Body,
                    encoding,
                    detectEncodingFromByteOrderMarks: true,
                    bufferSize: 1024,
                    leaveOpen: true))
                {
                    // The value length limit is enforced by
                    // MultipartBodyLengthLimit
                    var value = await streamReader.ReadToEndAsync();

                    if (string.Equals(value, "undefined",
                        StringComparison.OrdinalIgnoreCase))
                    {
                        value = string.Empty;
                    }

                    formAccumulator.Append(key, value);

                    if (formAccumulator.ValueCount >
                        _defaultFormOptions.ValueCountLimit)
                    {
                        // Form key count limit of
                        // _defaultFormOptions.ValueCountLimit
                        // is exceeded.
                        ModelState.AddModelError("File",
                            $"The request couldn't be processed (Error
3).");
                        // Log error

                        return BadRequest(ModelState);
                    }
                }
            }
        }

        // Drain any remaining section body that hasn't been consumed and
        // read the headers for the next section.
        section = await reader.ReadNextSectionAsync();
    }

    // Bind form data to the model
    var formData = new FormData();
    var formValueProvider = new FormValueProvider(
        BindingSource.Form,
        new FormCollection(formAccumulator.GetResults()),
        CultureInfo.CurrentCulture);
    var bindingSuccessful = await TryUpdateModelAsync(formData, prefix: "",
        valueProvider: formValueProvider);
```

```
    if (!bindingSuccessful)
    {
        ModelState.AddModelError("File",
            "The request couldn't be processed (Error 5).");
        // Log error

        return BadRequest(ModelState);
    }

    // **WARNING!**
    // In the following example, the file is saved without
    // scanning the file's contents. In most production
    // scenarios, an anti-virus/anti-malware scanner API
    // is used on the file before making the file available
    // for download or for use by other systems.
    // For more information, see the topic that accompanies
    // this sample app.

    var file = new AppFile()
    {
        Content = streamedFileContent,
        UntrustedName = untrustedFileNameForStorage,
        Note = formData.Note,
        Size = streamedFileContent.Length,
        UploadDT = DateTime.UtcNow
    };

    _context.File.Add(file);
    await _context.SaveChangesAsync();

    return Created(nameof(StreamingController), null);
}
```

`MultipartRequestHelper` (`Utilities/MultipartRequestHelper.cs`):

C#

```
using System;
using System.IO;
using Microsoft.Net.Http.Headers;

namespace SampleApp.Utilities
{
    public static class MultipartRequestHelper
    {
        // Content-Type: multipart/form-data; boundary="----
WebKitFormBoundarymx2fSWqWSd0OxQqq"
        // The spec at https://tools.ietf.org/html/rfc2046#section-5.1
states that 70 characters is a reasonable limit.
        public static string GetBoundary(MediaTypeHeaderValue contentType,
int lengthLimit)
        {
```

```
            var boundary =
HeaderUtilities.RemoveQuotes(contentType.Boundary).Value;

            if (string.IsNullOrWhiteSpace(boundary))
            {
                throw new InvalidDataException("Missing content-type
boundary.");
            }

            if (boundary.Length > lengthLimit)
            {
                throw new InvalidDataException(
                    $"Multipart boundary length limit {lengthLimit}
exceeded.");
            }

            return boundary;
        }

        public static bool IsMultipartContentType(string contentType)
        {
            return !string.IsNullOrEmpty(contentType)
                   && contentType.IndexOf("multipart/",
StringComparison.OrdinalIgnoreCase) >= 0;
        }

        public static bool
HasFormDataContentDisposition(ContentDispositionHeaderValue
contentDisposition)
        {
            // Content-Disposition: form-data; name="key";
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && string.IsNullOrEmpty(contentDisposition.FileName.Value)
                &&
string.IsNullOrEmpty(contentDisposition.FileNameStar.Value);
        }

        public static bool
HasFileContentDisposition(ContentDispositionHeaderValue contentDisposition)
        {
            // Content-Disposition: form-data; name="myfile1";
filename="Misc 002.jpg"
            return contentDisposition != null
                && contentDisposition.DispositionType.Equals("form-data")
                && (!string.IsNullOrEmpty(contentDisposition.FileName.Value)
                    ||
!string.IsNullOrEmpty(contentDisposition.FileNameStar.Value));
        }
    }
}
```

The complete `StreamingController.UploadPhysical` method for streaming to a physical location:

C#

```
[HttpPost]
[DisableFormValueModelBinding]
[ValidateAntiForgeryToken]
public async Task<IActionResult> UploadPhysical()
{
    if (!MultipartRequestHelper.IsMultipartContentType(Request.ContentType))
    {
        ModelState.AddModelError("File",
            $"The request couldn't be processed (Error 1).");
        // Log error

        return BadRequest(ModelState);
    }

    var boundary = MultipartRequestHelper.GetBoundary(
        MediaTypeHeaderValue.Parse(Request.ContentType),
        _defaultFormOptions.MultipartBoundaryLengthLimit);
    var reader = new MultipartReader(boundary, HttpContext.Request.Body);
    var section = await reader.ReadNextSectionAsync();

    while (section != null)
    {
        var hasContentDispositionHeader =
            ContentDispositionHeaderValue.TryParse(
                section.ContentDisposition, out var contentDisposition);

        if (hasContentDispositionHeader)
        {
            // This check assumes that there's a file
            // present without form data. If form data
            // is present, this method immediately fails
            // and returns the model error.
            if (!MultipartRequestHelper
                .HasFileContentDisposition(contentDisposition))
            {
                ModelState.AddModelError("File",
                    $"The request couldn't be processed (Error 2).");
                // Log error

                return BadRequest(ModelState);
            }
            else
            {
                // Don't trust the file name sent by the client. To display
                // the file name, HTML-encode the value.
                var trustedFileNameForDisplay = WebUtility.HtmlEncode(
                        contentDisposition.FileName.Value);
                var trustedFileNameForFileStorage =
Path.GetRandomFileName();
```

```
                // **WARNING!**
                // In the following example, the file is saved without
                // scanning the file's contents. In most production
                // scenarios, an anti-virus/anti-malware scanner API
                // is used on the file before making the file available
                // for download or for use by other systems.
                // For more information, see the topic that accompanies
                // this sample.

                var streamedFileContent = await
FileHelpers.ProcessStreamedFile(
                    section, contentDisposition, ModelState,
                    _permittedExtensions, _fileSizeLimit);

                if (!ModelState.IsValid)
                {
                    return BadRequest(ModelState);
                }

                using (var targetStream = System.IO.File.Create(
                    Path.Combine(_targetFilePath,
trustedFileNameForFileStorage)))
                {
                    await targetStream.WriteAsync(streamedFileContent);

                    _logger.LogInformation(
                        "Uploaded file '{TrustedFileNameForDisplay}' saved
to " +
                        "'{TargetFilePath}' as
{TrustedFileNameForFileStorage}",
                        trustedFileNameForDisplay, _targetFilePath,
                        trustedFileNameForFileStorage);
                }
            }
        }

        // Drain any remaining section body that hasn't been consumed and
        // read the headers for the next section.
        section = await reader.ReadNextSectionAsync();
    }

    return Created(nameof(StreamingController), null);
}
```

In the sample app, validation checks are handled by `FileHelpers.ProcessStreamedFile`.

Validation

The sample app's `FileHelpers` class demonstrates several checks for buffered IFormFile and streamed file uploads. For processing IFormFile buffered file uploads in the sample

app, see the `ProcessFormFile` method in the `Utilities/FileHelpers.cs` file. For processing streamed files, see the `ProcessStreamedFile` method in the same file.

> ⚠ **Warning**
>
> The validation processing methods demonstrated in the sample app don't scan the content of uploaded files. In most production scenarios, a virus/malware scanner API is used on the file before making the file available to users or other systems.
>
> Although the topic sample provides a working example of validation techniques, don't implement the `FileHelpers` class in a production app unless you:
>
> - Fully understand the implementation.
> - Modify the implementation as appropriate for the app's environment and specifications.
>
> **Never indiscriminately implement security code in an app without addressing these requirements.**

Content validation

Use a third party virus/malware scanning API on uploaded content.

Scanning files is demanding on server resources in high volume scenarios. If request processing performance is diminished due to file scanning, consider offloading the scanning work to a background service, possibly a service running on a server different from the app's server. Typically, uploaded files are held in a quarantined area until the background virus scanner checks them. When a file passes, the file is moved to the normal file storage location. These steps are usually performed in conjunction with a database record that indicates the scanning status of a file. By using such an approach, the app and app server remain focused on responding to requests.

File extension validation

The uploaded file's extension should be checked against a list of permitted extensions. For example:

C#

```
private string[] permittedExtensions = { ".txt", ".pdf" };

var ext = Path.GetExtension(uploadedFileName).ToLowerInvariant();
```

```
if (string.IsNullOrEmpty(ext) || !permittedExtensions.Contains(ext))
{
    // The extension is invalid ... discontinue processing the file
}
```

File signature validation

A file's signature is determined by the first few bytes at the start of a file. These bytes can be used to indicate if the extension matches the content of the file. The sample app checks file signatures for a few common file types. In the following example, the file signature for a JPEG image is checked against the file:

C#

```
private static readonly Dictionary<string, List<byte[]>> _fileSignature =
    new Dictionary<string, List<byte[]>>
{
    { ".jpeg", new List<byte[]>
        {
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE0 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE2 },
            new byte[] { 0xFF, 0xD8, 0xFF, 0xE3 },
        }
    },
};

using (var reader = new BinaryReader(uploadedFileData))
{
    var signatures = _fileSignature[ext];
    var headerBytes = reader.ReadBytes(signatures.Max(m => m.Length));

    return signatures.Any(signature =>
        headerBytes.Take(signature.Length).SequenceEqual(signature));
}
```

To obtain additional file signatures, use a file signatures database (Google search result) and official file specifications. Consulting official file specifications may ensure that the selected signatures are valid.

File name security

Never use a client-supplied file name for saving a file to physical storage. Create a safe file name for the file using Path.GetRandomFileName or Path.GetTempFileName to create a full path (including the file name) for temporary storage.

Razor automatically HTML encodes property values for display. The following code is safe to use:

CSHTML

```
@foreach (var file in Model.DatabaseFiles) {
    <tr>
        <td>
            @file.UntrustedName
        </td>
    </tr>
}
```

Outside of Razor, always HtmlEncode file name content from a user's request.

Many implementations must include a check that the file exists; otherwise, the file is overwritten by a file of the same name. Supply additional logic to meet your app's specifications.

Size validation

Limit the size of uploaded files.

In the sample app, the size of the file is limited to 2 MB (indicated in bytes). The limit is supplied via Configuration from the `appsettings.json` file:

JSON

```
{
  "FileSizeLimit": 2097152
}
```

The `FileSizeLimit` is injected into `PageModel` classes:

C#

```
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    private readonly long _fileSizeLimit;

    public BufferedSingleFileUploadPhysicalModel(IConfiguration config)
    {
        _fileSizeLimit = config.GetValue<long>("FileSizeLimit");
    }
```

```
    ...
}
```

When a file size exceeds the limit, the file is rejected:

C#

```
if (formFile.Length > _fileSizeLimit)
{
    // The file is too large ... discontinue processing the file
}
```

Match name attribute value to parameter name of POST method

In non-Razor forms that POST form data or use JavaScript's `FormData` directly, the name specified in the form's element or `FormData` must match the name of the parameter in the controller's action.

In the following example:

- When using an `<input>` element, the `name` attribute is set to the value `battlePlans`:

  HTML

  ```
  <input type="file" name="battlePlans" multiple>
  ```

- When using `FormData` in JavaScript, the name is set to the value `battlePlans`:

  JavaScript

  ```
  var formData = new FormData();

  for (var file in files) {
    formData.append("battlePlans", file, file.name);
  }
  ```

Use a matching name for the parameter of the C# method (`battlePlans`):

- For a Razor Pages page handler method named `Upload`:

  C#

```
public async Task<IActionResult> OnPostUploadAsync(List<IFormFile>
battlePlans)
```

- For an MVC POST controller action method:

```
C#

public async Task<IActionResult> Post(List<IFormFile> battlePlans)
```

Server and app configuration

Multipart body length limit

MultipartBodyLengthLimit sets the limit for the length of each multipart body. Form sections that exceed this limit throw an InvalidDataException when parsed. The default is 134,217,728 (128 MB). Customize the limit using the MultipartBodyLengthLimit setting in `Startup.ConfigureServices`:

```
C#

public void ConfigureServices(IServiceCollection services)
{
    services.Configure<FormOptions>(options =>
    {
        // Set the limit to 256 MB
        options.MultipartBodyLengthLimit = 268435456;
    });
}
```

RequestFormLimitsAttribute is used to set the MultipartBodyLengthLimit for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

```
C#

services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/FileUploadPage",
            model.Filters.Add(
                new RequestFormLimitsAttribute()
                {
                    // Set the limit to 256 MB
```

```
                    MultipartBodyLengthLimit = 268435456
                });
});
```

In a Razor Pages app or an MVC app, apply the filter to the page model or action method:

C#

```
// Set the limit to 256 MB
[RequestFormLimits(MultipartBodyLengthLimit = 268435456)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

Kestrel maximum request body size

For apps hosted by Kestrel, the default maximum request body size is 30,000,000 bytes, which is approximately 28.6 MB. Customize the limit using the MaxRequestBodySize Kestrel server option:

C#

```
public static IHostBuilder CreateHostBuilder(string[] args) =>
    Host.CreateDefaultBuilder(args)
        .ConfigureWebHostDefaults(webBuilder =>
        {
            webBuilder.ConfigureKestrel((context, options) =>
            {
                // Handle requests up to 50 MB
                options.Limits.MaxRequestBodySize = 52428800;
            })
            .UseStartup<Startup>();
        });
```

RequestSizeLimitAttribute is used to set the MaxRequestBodySize for a single page or action.

In a Razor Pages app, apply the filter with a convention in `Startup.ConfigureServices`:

C#

```
services.AddRazorPages(options =>
{
    options.Conventions
        .AddPageApplicationModelConvention("/FileUploadPage",
```

```
            model =>
            {
                // Handle requests up to 50 MB
                model.Filters.Add(
                    new RequestSizeLimitAttribute(52428800));
            });
});
```

In a Razor pages app or an MVC app, apply the filter to the page handler class or action method:

C#

```
// Handle requests up to 50 MB
[RequestSizeLimit(52428800)]
public class BufferedSingleFileUploadPhysicalModel : PageModel
{
    ...
}
```

The `RequestSizeLimitAttribute` can also be applied using the @attribute Razor directive:

CSHTML

```
@attribute [RequestSizeLimitAttribute(52428800)]
```

Other Kestrel limits

Other Kestrel limits may apply for apps hosted by Kestrel:

- Maximum client connections
- Request and response data rates

IIS

The default request limit (`maxAllowedContentLength`) is 30,000,000 bytes, which is approximately 28.6 MB. Customize the limit in the `web.config` file. In the following example, the limit is set to 50 MB (52,428,800 bytes):

XML

```
<system.webServer>
  <security>
    <requestFiltering>
```

```
      <requestLimits maxAllowedContentLength="52428800" />
    </requestFiltering>
  </security>
</system.webServer>
```

The `maxAllowedContentLength` setting only applies to IIS. For more information, see Request Limits <requestLimits>.

Troubleshoot

Below are some common problems encountered when working with uploading files and their possible solutions.

Not Found error when deployed to an IIS server

The following error indicates that the uploaded file exceeds the server's configured content length:

```
HTTP 404.13 - Not Found
The request filtering module is configured to deny a request that exceeds
the request content length.
```

For more information, see the IIS section.

Connection failure

A connection error and a reset server connection probably indicates that the uploaded file exceeds Kestrel's maximum request body size. For more information, see the Kestrel maximum request body size section. Kestrel client connection limits may also require adjustment.

Null Reference Exception with IFormFile

If the controller is accepting uploaded files using IFormFile but the value is `null`, confirm that the HTML form is specifying an `enctype` value of `multipart/form-data`. If this attribute isn't set on the `<form>` element, the file upload doesn't occur and any bound IFormFile arguments are `null`. Also confirm that the upload naming in form data matches the app's naming.

Stream was too long

The examples in this topic rely upon MemoryStream to hold the uploaded file's content. The size limit of a `MemoryStream` is `int.MaxValue`. If the app's file upload scenario requires holding file content larger than 50 MB, use an alternative approach that doesn't rely upon a single `MemoryStream` for holding an uploaded file's content.

ASP.NET Core Web SDK

Article • 04/10/2024

Overview

`Microsoft.NET.Sdk.Web` is an MSBuild project SDK for building ASP.NET Core apps. It's possible to build an ASP.NET Core app without this SDK, however, the Web SDK is:

- Tailored towards providing a first-class experience.
- The recommended target for most users.

Use the Web.SDK in a project:

XML

```xml
<Project Sdk="Microsoft.NET.Sdk.Web">
  <!-- omitted for brevity -->
</Project>
```

Features enabled by using the Web SDK:

- Implicitly references:
  - The ASP.NET Core shared framework.
  - Analyzers designed for building ASP.NET Core apps.
- The Web SDK imports MSBuild targets that enable the use of publish profiles and publishing using WebDeploy.

Properties

Expand table

Property	Description
`DisableImplicitFrameworkReferences`	Disables implicit reference to the `Microsoft.AspNetCore.App` shared framework.
`DisableImplicitAspNetCoreAnalyzers`	Disables implicit reference to ASP.NET Core analyzers.
`DisableImplicitComponentsAnalyzers`	Disables implicit reference to Razor Components analyzers when building Blazor (server) applications.

For more information on tasks, targets, properties, implicit blobs, globs, publishing, methods, and more, see the README file in the WebSdk repository.

ASP.NET Core code generator tool (`aspnet-codegenerator`)

Article • 08/06/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

The `dotnet aspnet-codegenerator` command runs the ASP.NET Core scaffolding engine. Running the `dotnet aspnet-codegenerator` command is required to scaffold from the command line or when using Visual Studio Code. The command isn't required to use scaffolding with Visual Studio, which includes the scaffolding engine by default.

Install and update the code generator tool

Install the .NET SDK.

`dotnet aspnet-codegenerator` is a global tool that must be installed. The following command installs the latest stable version of the ASP.NET Core code generator tool:

.NET CLI

```
dotnet tool install -g dotnet-aspnet-codegenerator
```

> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see dotnet tool install, --arch option. For more information, see GitHub issue dotnet/AspNetCore.Docs #29262.

If the tool is already installed, the following command updates the tool to the latest stable version available from the installed .NET Core SDKs:

.NET CLI

```
dotnet tool update -g dotnet-aspnet-codegenerator
```

Uninstall the code generator tool

It may be necessary to uninstall the ASP.NET Core code generator tool to resolve problems. For example, if you installed a preview version of the tool, uninstall it before installing the released version.

The following commands uninstall the ASP.NET Core code generator tool and install the latest stable version:

.NET CLI

```
dotnet tool uninstall -g dotnet-aspnet-codegenerator
dotnet tool install -g dotnet-aspnet-codegenerator
```

Synopsis

```
dotnet aspnet-codegenerator [arguments] [-b|--build-base-path] [-c|--
configuration] [-n|--nuget-package-dir] [--no-build] [-p|--project] [-tfm|--
target-framework]
dotnet aspnet-codegenerator [-h|--help]
```

Description

The `dotnet aspnet-codegenerator` global command runs the ASP.NET Core code generator and scaffolding engine.

Arguments

`generator`

The code generator to run. The available generators are shown in the following table.

Expand table

Generator	Operation
`area`	Scaffolds an area.
`blazor`	Scaffolds Blazor create, read, update, delete, and list pages.
`blazor-identity`	Generates Blazor Identity files.
`controller`	Scaffolds a controller.
`identity`	Scaffolds Identity.
`minimalapi`	Generates an endpoints file (with CRUD API endpoints) given a model and optional database context.
`razorpage`	Scaffolds Razor Pages.
`view`	Scaffolds a view.

Options

`-b|--build-base-path`

The build base path.

`-c|--configuration {Debug|Release}`

Defines the build configuration. The default value is `Debug`.

`-h|--help`

Prints out a short help for the command.

`-n|--nuget-package-dir`

Specifies the NuGet package directory.

`--no-build`

Doesn't build the project before running. Passing `--no-build` also implicitly sets the `--no-restore` flag.

`-p|--project <PATH>`

Specifies the path of the project file to run (folder name or full path). If not specified, the tool defaults to the current directory.

`-tfm|--target-framework`

The target framework to use.

Generator options

The following sections detail the options available for the supported generators:

- Area (area)
- Controller (controller)
- Blazor (blazor)
- Blazor Identity (blazor-identity)
- Identity (identity)
- Minimal API (minimalapi)
- Razor page (razorpage)
- View (view)

Area options

Usage: `dotnet aspnet-codegenerator area {AREA NAME}`

The `{AREA NAME}` placeholder is the name of the area to generate.

The preceding command generates the following folders:

- `Areas`
  - `{AREA NAME}`
    - `Controllers`
    - `Data`
    - `Models`
    - `Views`

Use the `-h|--help` option for help:

.NET CLI

```
dotnet aspnet-codegenerator area -h
```

Blazor options

Razor components can be individually scaffolded for Blazor apps by specifying the name of the template to use. The supported templates are:

- `Empty`
- `Create`
- `Edit`
- `Delete`
- `Details`
- `List`
- `CRUD`: *CRUD* is an acronym for Create, Read, Update, and Delete. The `CRUD` template produces `Create`, `Edit`, `Delete`, `Details`, and `Index` (`List`) components for the app.

The options for the `blazor` generator are shown in the following table.

Expand table

Option	Description
`-dbProvider|--databaseProvider`	Database provider to use. Options include `sqlserver` (default), `sqlite`, `cosmos`, or `postgres`.
`-dc|--dataContext`	Database context class to use.
`-m|--model`	Model class to use.
`-ns|--namespaceName`	Specify the name of the namespace to use for the generated Endpoints file.
`--relativeFolderPath|-outDir`	Relative output folder path. If not specified, files are generated in the project folder.

The following example:

- Uses the `Edit` template to generate an `Edit` component (`Edit.razor`) in the `Components/Pages/MoviePages` folder of the app. If the `MoviePages` folder doesn't exist, the tool creates the folder automatically.
- Uses the SQLite database provider.
- Uses `BlazorWebAppMovies.Data.BlazorWebAppMoviesContext` for the database context.
- Uses the `Movie` model.

.NET CLI

```
dotnet aspnet-codegenerator blazor Edit -dbProvider sqlite -dc
BlazorWebAppMovies.Data.BlazorWebAppMoviesContext -m Movie -outDir
Components/Pages
```

Use the `-h|--help` option for help:

.NET CLI

```
dotnet aspnet-codegenerator blazor -h
```

For more information, see ASP.NET Core Blazor QuickGrid component.

Blazor Identity options

Scaffold Identity Razor components into a Blazor app with the `blazor-identity` generator.

The options for the `blazor-identity` template are shown in the following table.

Expand table

Option	Description
`-dbProvider|--databaseProvider`	Database provider to use. Options include `sqlserver` (default) and `sqlite`.
`-dc|--dataContext`	Database context class to use.
`-f|--force`	Use this option to overwrite existing files.
`-fi|--files`	List of semicolon separated files to scaffold. Use the `-lf|--listFiles` option to see the available options.
`-lf|--listFiles`	Lists the files that can be scaffolded by using the `-fi|--files` option.
`-rn|--rootNamespace`	Root namespace to use for generating Identity code.
`-u|--userClass`	Name of the user class to generate.

Use the `-h|--help` option for help:

.NET CLI

```
dotnet aspnet-codegenerator blazor-identity -h
```

Controller options

General options are shown in the following table.

Expand table

Option	Description
`-b|--bootstrapVersion`	Specifies the bootstrap version and creates a `wwwroot` folder for the Bootstrap assets if the folder isn't present.
`-dbProvider|--databaseProvider`	Database provider to use. Options include `sqlserver` (default), `sqlite`, `cosmos`, `postgres`.
`-dc|--dataContext`	The database context class to use or the name of the class to generate.
`-f|--force`	Overwrite existing files.
`-l|--layout`	Custom layout page to use.
`-m|--model`	Model class to use.
`-outDir|--relativeFolderPath`	Relative output folder path. If not specified, files are generated in the project folder.
`-scripts|--referenceScriptLibraries`	Reference script libraries in the generated views. Adds `_ValidationScriptsPartial` to `Edit` and `Create` pages.
`-sqlite|--useSqlite`	Flag to specify if the database context should use SQLite instead of SQL Server.
`-udl|--useDefaultLayout`	Use the default layout for the views.

The options unique to `controller` are shown in the following table.

Expand table

Option	Description
`-actions|--readWriteActions`	Generate controller with read/write actions without a model.
`-api|--restWithNoViews`	Generate a controller with REST style API. `noViews` is assumed and any view related options are ignored.
`-async|--useAsyncActions`	Generate asynchronous controller actions.
`-name|--controllerName`	Name of the controller.
`-namespace|--controllerNamespace`	Specify the name of the namespace to use for the generated controller.
`-nv|--noViews`	Generate **no** views.

Use the `-h|--help` option for help:

.NET CLI

```
dotnet aspnet-codegenerator controller -h
```

For an example that uses the `controller` generator, see Part 4, add a model to an ASP.NET Core MVC app.

Identity options

For more information, see Scaffold Identity in ASP.NET Core projects.

Minimal API options

Scaffold a Minimal API backend with the `minimalapi` template.

The options for `minimalapi` are shown in the following table.

Expand table

Option	Description
`-dbProvider|--databaseProvider`	Database provider to use. Options include `sqlserver` (default), `sqlite`, `cosmos`, or `postgres`.
`-dc|--dataContext`	Database context class to use.
`-e|--endpoints`	Endpoints class to use (not the file name).
`-m|--model`	Model class to use.
`-namespace|--endpointsNamespace`	Specify the name of the namespace to use for the generated endpoints file.
`-o|--open`	Use this option to enable OpenAPI.
`-outDir|--relativeFolderPath`	Relative output folder path. If not specified, files are generated in the project folder.
`-sqlite|--useSqlite`	Flag to specify if the database context should use SQLite instead of SQL Server.

The following example:

- Generates an endpoints class named `SpeakersEndpoints` with API endpoints that map to database operations using the `ApplicationDbContext` database context class and the `BackEnd.Models.Speaker` model.
- Adds `app.MapSpeakerEndpoints();` to the `Program` file (`Program.cs`) to register the endpoints class.

.NET CLI

```
dotnet aspnet-codegenerator minimalapi -dc ApplicationDbContext -e
SpeakerEndpoints -m BackEnd.Models.Speaker -o
```

Use the `-h|--help` option for help:

.NET CLI

```
dotnet aspnet-codegenerator minimalapi -h
```

Razor page options

Razor Pages can be individually scaffolded by specifying the name of the new page and the template to use. The supported templates are:

- `Empty`
- `Create`
- `Edit`
- `Delete`
- `Details`
- `List`

Typically, the template and generated file name isn't specified, which creates the following templates:

- `Create`
- `Edit`
- `Delete`
- `Details`
- `List`

General options are shown in the following table.

Expand table

Option	Description
`-b|--bootstrapVersion`	Specifies the bootstrap version and creates a `wwwroot` folder for the Bootstrap assets if the folder isn't present.
`-dbProvider|--databaseProvider`	Database provider to use. Options include `sqlserver` (default), `sqlite`, `cosmos`, `postgres`.
`-dc|--dataContext`	The database context class to use or the name of the class to generate.
`-f|--force`	Overwrite existing files.
`-l|--layout`	Custom layout page to use.
`-m|--model`	Model class to use.
`-outDir|--relativeFolderPath`	Relative output folder path. If not specified, files are generated in the project folder.
`-scripts|--referenceScriptLibraries`	Reference script libraries in the generated views. Adds `_ValidationScriptsPartial` to `Edit` and `Create` pages.
`-sqlite|--useSqlite`	Flag to specify if the database context should use SQLite instead of SQL Server.
`-udl|--useDefaultLayout`	Use the default layout for the views.

The options unique to `razorpage` are shown in the following table.

Expand table

Option	Description
`-namespace|--namespaceName`	The name of the namespace to use for the generated `PageModel` class.
`-npm|--noPageModel`	Don't generate a `PageModel` class for the `Empty` template.
`-partial|--partialView`	Generate a partial view. Layout options `-l` and `-udl` are ignored if this is specified.

The following example uses the `Edit` template to generate `CustomEditPage.cshtml` and `CustomEditPage.cshtml.cs` in the `Pages/Movies` folder:

.NET CLI

```
dotnet aspnet-codegenerator razorpage CustomEditPage Edit -dc
```

```
RazorPagesMovieContext -m Movie -outDir Pages/Movies
```

Use the `-h|--help` option for help:

.NET CLI

```
dotnet aspnet-codegenerator razorpage -h
```

For an example that uses the `razorpage` generator, see Part 2, add a model.

View options

Views can be individually scaffolded by specifying the name of the view and the template. The supported templates are:

- `Empty`
- `Create`
- `Edit`
- `Delete`
- `Details`
- `List`

General options are shown in the following table.

Expand table

Option	Description
`-b|--bootstrapVersion`	Specifies the bootstrap version and creates a `wwwroot` folder for the Bootstrap assets if the folder isn't present.
`-dbProvider|--databaseProvider`	Database provider to use. Options include `sqlserver` (default), `sqlite`, `cosmos`, `postgres`.
`-dc|--dataContext`	The database context class to use or the name of the class to generate.
`-f|--force`	Overwrite existing files.
`-l|--layout`	Custom layout page to use.
`-m|--model`	Model class to use.
`-outDir|--relativeFolderPath`	Relative output folder path. If not specified, files are generated in the project folder.

Option	Description
`-scripts|--referenceScriptLibraries`	Reference script libraries in the generated views. Adds `_ValidationScriptsPartial` to `Edit` and `Create` pages.
`-sqlite|--useSqlite`	Flag to specify if the database context should use SQLite instead of SQL Server.
`-udl|--useDefaultLayout`	Use the default layout for the views.

The options unique to `view` are shown in the following table.

Expand table

Option	Description
`-namespace|--controllerNamespace`	Specify the name of the namespace to use for the generated controller.
`-partial|--partialView`	Generate a partial view. Other layout options (`-l` and `-udl`) are ignored if this is specified.

The following example uses the `Edit` template to generate `CustomEditView.cshtml` in the `Views/Movies` folder:

.NET CLI

```
dotnet aspnet-codegenerator view CustomEditView Edit -dc MovieContext -m
Movie -outDir Views/Movies
```

Use the `-h|--help` option for help:

.NET CLI

```
dotnet aspnet-codegenerator view -h
```

Choose between controller-based APIs and minimal APIs

Article • 04/11/2023

ASP.NET Core supports two approaches to creating APIs: a controller-based approach and minimal APIs. *Controllers* in an API project are classes that derive from ControllerBase. *Minimal APIs* define endpoints with logical handlers in lambdas or methods. This article points out differences between the two approaches.

The design of minimal APIs hides the host class by default and focuses on configuration and extensibility via extension methods that take functions as lambda expressions. Controllers are classes that can take dependencies via constructor injection or property injection, and generally follow object-oriented patterns. Minimal APIs support dependency injection through other approaches such as accessing the service provider.

Here's sample code for an API based on controllers:

C#

```
namespace APIWithControllers;

public class Program
{
    public static void Main(string[] args)
    {
        var builder = WebApplication.CreateBuilder(args);

        builder.Services.AddControllers();
        var app = builder.Build();

        app.UseHttpsRedirection();

        app.MapControllers();

        app.Run();
    }
}
```

C#

```
using Microsoft.AspNetCore.Mvc;

namespace APIWithControllers.Controllers;
[ApiController]
[Route("[controller]")]
```

```
public class WeatherForecastController : ControllerBase
{
    private static readonly string[] Summaries = new[]
    {
        "Freezing", "Bracing", "Chilly", "Cool", "Mild", "Warm", "Balmy",
"Hot", "Sweltering", "Scorching"
    };

    private readonly ILogger<WeatherForecastController> _logger;

    public WeatherForecastController(ILogger<WeatherForecastController>
logger)
    {
        _logger = logger;
    }

    [HttpGet(Name = "GetWeatherForecast")]
    public IEnumerable<WeatherForecast> Get()
    {
        return Enumerable.Range(1, 5).Select(index => new WeatherForecast
        {
            Date = DateOnly.FromDateTime(DateTime.Now.AddDays(index)),
            TemperatureC = Random.Shared.Next(-20, 55),
            Summary = Summaries[Random.Shared.Next(Summaries.Length)]
        })
        .ToArray();
    }
}
```

The following code provides the same functionality in a minimal API project. Notice that the minimal API approach involves including the related code in lambda expressions.

C#

```
namespace MinimalAPI;

public class Program
{
    public static void Main(string[] args)
    {
        var builder = WebApplication.CreateBuilder(args);

        var app = builder.Build();

        app.UseHttpsRedirection();

        var summaries = new[]
        {
            "Freezing", "Bracing", "Chilly", "Cool", "Mild", "Warm",
"Balmy", "Hot", "Sweltering", "Scorching"
        };
```

```
        app.MapGet("/weatherforecast", (HttpContext httpContext) =>
        {
            var forecast = Enumerable.Range(1, 5).Select(index =>
                new WeatherForecast
                {
                    Date =
DateOnly.FromDateTime(DateTime.Now.AddDays(index)),
                    TemperatureC = Random.Shared.Next(-20, 55),
                    Summary =
summaries[Random.Shared.Next(summaries.Length)]
                })
                .ToArray();
            return forecast;
        });

        app.Run();
    }
}
```

Both API projects refer to the following class:

C#

```
namespace APIWithControllers;

public class WeatherForecast
{
    public DateOnly Date { get; set; }

    public int TemperatureC { get; set; }

    public int TemperatureF => 32 + (int)(TemperatureC / 0.5556);

    public string? Summary { get; set; }
}
```

Minimal APIs have many of the same capabilities as controller-based APIs. They support the configuration and customization needed to scale to multiple APIs, handle complex routes, apply authorization rules, and control the content of API responses. There are a few capabilities available with controller-based APIs that are not yet supported or implemented by minimal APIs. These include:

- No built-in support for model binding (IModelBinderProvider, IModelBinder). Support can be added with a custom binding shim.
- No built-in support for validation (IModelValidator).
- No support for application parts or the application model. There's no way to apply or build your own conventions.

- No built-in view rendering support. We recommend using Razor Pages for rendering views.
- No support for JsonPatch
- No support for OData

Create web APIs with ASP.NET Core

Article • 05/29/2024

ASP.NET Core supports creating web APIs using controllers or using minimal APIs. *Controllers* in a web API are classes that derive from ControllerBase. Controllers are activated and disposed on a per request basis.

This article shows how to use controllers for handling web API requests. For information on creating web APIs without controllers, see Tutorial: Create a minimal API with ASP.NET Core.

ControllerBase class

A controller-based web API consists of one or more controller classes that derive from ControllerBase. The web API project template provides a starter controller:

C#

```
[ApiController]
[Route("[controller]")]
public class WeatherForecastController : ControllerBase
```

Web API controllers should typically derive from ControllerBase rather from Controller. `Controller` derives from ControllerBase and adds support for views, so it's for handling web pages, not web API requests. If the same controller must support views and web APIs, derive from `Controller`.

The `ControllerBase` class provides many properties and methods that are useful for handling HTTP requests. For example, CreatedAtAction returns a 201 status code:

C#

```
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<Pet> Create(Pet pet)
{
    pet.Id = _petsInMemoryStore.Any() ?
             _petsInMemoryStore.Max(p => p.Id) + 1 : 1;
    _petsInMemoryStore.Add(pet);

    return CreatedAtAction(nameof(GetById), new { id = pet.Id }, pet);
}
```

The following table contains examples of methods in `ControllerBase`.

Expand table

Method	Notes
BadRequest	Returns 400 status code.
NotFound	Returns 404 status code.
PhysicalFile	Returns a file.
TryUpdateModelAsync	Invokes model binding.
TryValidateModel	Invokes model validation.

For a list of all available methods and properties, see ControllerBase.

Attributes

The Microsoft.AspNetCore.Mvc namespace provides attributes that can be used to configure the behavior of web API controllers and action methods. The following example uses attributes to specify the supported HTTP action verb and any known HTTP status codes that could be returned:

C#

```
[HttpPost]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public ActionResult<Pet> Create(Pet pet)
{
    pet.Id = _petsInMemoryStore.Any() ?
             _petsInMemoryStore.Max(p => p.Id) + 1 : 1;
    _petsInMemoryStore.Add(pet);

    return CreatedAtAction(nameof(GetById), new { id = pet.Id }, pet);
}
```

Here are some more examples of attributes that are available.

Expand table

Attribute	Notes
[Route]	Specifies URL pattern for a controller or action.

Attribute	Notes
[Bind]	Specifies prefix and properties to include for model binding.
[HttpGet]	Identifies an action that supports the HTTP GET action verb.
[Consumes]	Specifies data types that an action accepts.
[Produces]	Specifies data types that an action returns.

For a list that includes the available attributes, see the Microsoft.AspNetCore.Mvc namespace.

ApiController attribute

The [ApiController] attribute can be applied to a controller class to enable the following opinionated, API-specific behaviors:

- Attribute routing requirement
- Automatic HTTP 400 responses
- Binding source parameter inference
- Multipart/form-data request inference
- Problem details for error status codes

Attribute on specific controllers

The `[ApiController]` attribute can be applied to specific controllers, as in the following example from the project template:

C#

```
[ApiController]
[Route("[controller]")]
public class WeatherForecastController : ControllerBase
```

Attribute on multiple controllers

One approach to using the attribute on more than one controller is to create a custom base controller class annotated with the [ApiController] attribute. The following example shows a custom base class and a controller that derives from it:

C#

```
[ApiController]
public class MyControllerBase : ControllerBase
{
}
```

C#

```
[Produces(MediaTypeNames.Application.Json)]
[Route("[controller]")]
public class PetsController : MyControllerBase
```

Attribute on an assembly

The `[ApiController]` attribute can be applied to an assembly. When the `[ApiController]` attribute is applied to an assembly, all controllers in the assembly have the `[ApiController]` attribute applied. There's no way to opt out for individual controllers. Apply the assembly-level attribute to the `Program.cs` file:

C#

```
using Microsoft.AspNetCore.Mvc;
[assembly: ApiController]
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Attribute routing requirement

The `[ApiController]` attribute makes attribute routing a requirement. For example:

C#

```
[ApiController]
[Route("[controller]")]
```

```
public class WeatherForecastController : ControllerBase
```

Actions are inaccessible via conventional routes defined by `UseEndpoints`, UseMvc, or UseMvcWithDefaultRoute.

Automatic HTTP 400 responses

The `[ApiController]` attribute makes model validation errors automatically trigger an HTTP 400 response. Consequently, the following code is unnecessary in an action method:

C#

```
if (!ModelState.IsValid)
{
    return BadRequest(ModelState);
}
```

ASP.NET Core MVC uses the ModelStateInvalidFilter action filter to do the preceding check.

Default BadRequest response

The default response type for an HTTP 400 response is ValidationProblemDetails. The following response body is an example of the serialized type:

JSON

```
{
  "type": "https://tools.ietf.org/html/rfc7231#section-6.5.1",
  "title": "One or more validation errors occurred.",
  "status": 400,
  "traceId": "|7fb5e16a-4c8f23bbfc974667.",
  "errors": {
    "": [
      "A non-empty request body is required."
    ]
  }
}
```

The `ValidationProblemDetails` type:

- Provides a machine-readable format for specifying errors in web API responses.
- Complies with the RFC 7807 specification.

To make automatic and custom responses consistent, call the ValidationProblem method instead of BadRequest. `ValidationProblem` returns a ValidationProblemDetails object as well as the automatic response.

Log automatic 400 responses

To log automatic 400 responses, set the InvalidModelStateResponseFactory delegate property to perform custom processing. By default, `InvalidModelStateResponseFactory` uses ProblemDetailsFactory to create an instance of ValidationProblemDetails.

The following example shows how to retrieve an instance of ILogger<TCategoryName> to log information about an automatic 400 response:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
      // To preserve the default behavior, capture the original delegate to
call later.
        var builtInFactory = options.InvalidModelStateResponseFactory;

        options.InvalidModelStateResponseFactory = context =>
        {
            var logger = context.HttpContext.RequestServices
                                .GetRequiredService<ILogger<Program>>();

            // Perform logging here.
            // ...

            // Invoke the default behavior, which produces a
ValidationProblemDetails
            // response.
            // To produce a custom response, return a different
implementation of
            // IActionResult instead.
            return builtInFactory(context);
        };
    });

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();
```

```
app.Run();
```

Disable automatic 400 response

To disable the automatic 400 behavior, set the SuppressModelStateInvalidFilter property to `true`. Add the following highlighted code:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Binding source parameter inference

A binding source attribute defines the location at which an action parameter's value is found. The following binding source attributes exist:

Expand table

Attribute	Binding source
[FromBody]	Request body
[FromForm]	Form data in the request body

Attribute	Binding source
[FromHeader]	Request header
[FromQuery]	Request query string parameter
[FromRoute]	Route data from the current request
[FromServices]	The request service injected as an action parameter
[AsParameters]	Method parameters

> ⚠ **Warning**
>
> Don't use `[FromRoute]` when values might contain `%2f` (that is `/`). `%2f` won't be unescaped to `/`. Use `[FromQuery]` if the value might contain `%2f`.

Without the `[ApiController]` attribute or binding source attributes like `[FromQuery]`, the ASP.NET Core runtime attempts to use the complex object model binder. The complex object model binder pulls data from value providers in a defined order.

In the following example, the `[FromQuery]` attribute indicates that the `discontinuedOnly` parameter value is provided in the request URL's query string:

C#

```
[HttpGet]
public ActionResult<List<Product>> Get(
    [FromQuery] bool discontinuedOnly = false)
{
    List<Product> products = null;

    if (discontinuedOnly)
    {
        products = _productsInMemoryStore.Where(p =>
p.IsDiscontinued).ToList();
    }
    else
    {
        products = _productsInMemoryStore;
    }

    return products;
}
```

The `[ApiController]` attribute applies inference rules for the default data sources of action parameters. These rules save you from having to identify binding sources

manually by applying attributes to the action parameters. The binding source inference rules behave as follows:

- `[FromServices]` is inferred for complex type parameters registered in the DI Container.
- `[FromBody]` is inferred for complex type parameters not registered in the DI Container. An exception to the `[FromBody]` inference rule is any complex, built-in type with a special meaning, such as IFormCollection and CancellationToken. The binding source inference code ignores those special types.
- `[FromForm]` is inferred for action parameters of type IFormFile and IFormFileCollection. It's not inferred for any simple or user-defined types.
- `[FromRoute]` is inferred for any action parameter name matching a parameter in the route template. When more than one route matches an action parameter, any route value is considered `[FromRoute]`.
- `[FromQuery]` is inferred for any other action parameters.

FromBody inference notes

`[FromBody]` isn't inferred for simple types such as `string` or `int`. Therefore, the `[FromBody]` attribute should be used for simple types when that functionality is needed.

When an action has more than one parameter bound from the request body, an exception is thrown. For example, all of the following action method signatures cause an exception:

- `[FromBody]` inferred on both because they're complex types.

  C#

  ```
  [HttpPost]
  public IActionResult Action1(Product product, Order order)
  ```

- `[FromBody]` attribute on one, inferred on the other because it's a complex type.

  C#

  ```
  [HttpPost]
  public IActionResult Action2(Product product, [FromBody] Order order)
  ```

- `[FromBody]` attribute on both.

  C#

```
[HttpPost]
public IActionResult Action3([FromBody] Product product, [FromBody]
Order order)
```

FromServices inference notes

Parameter binding binds parameters through dependency injection when the type is configured as a service. This means it's not required to explicitly apply the [FromServices] attribute to a parameter. In the following code, both actions return the time:

C#

```
[Route("[controller]")]
[ApiController]
public class MyController : ControllerBase
{
    public ActionResult GetWithAttribute([FromServices] IDateTime dateTime)
                                                        => Ok(dateTime.Now);

    [Route("noAttribute")]
    public ActionResult Get(IDateTime dateTime) => Ok(dateTime.Now);
}
```

In rare cases, automatic DI can break apps that have a type in DI that is also accepted in an API controller's action methods. It's not common to have a type in DI and as an argument in an API controller action.

To disable `[FromServices]` inference for a single action parameter, apply the desired binding source attribute to the parameter. For example, apply the `[FromBody]` attribute to an action parameter that should be bound from the body of the request.

To disable `[FromServices]` inference globally, set DisableImplicitFromServicesParameters to `true`:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddSingleton<IDateTime, SystemDateTime>();
```

```
builder.Services.Configure<ApiBehaviorOptions>(options =>
{
    options.DisableImplicitFromServicesParameters = true;
});

var app = builder.Build();

app.MapControllers();

app.Run();
```

Types are checked at app startup with IServiceProviderIsService to determine if an argument in an API controller action comes from DI or from the other sources.

The mechanism to infer binding source of API Controller action parameters uses the following rules:

- A previously specified BindingInfo.BindingSource is never overwritten.
- A complex type parameter, registered in the DI container, is assigned BindingSource.Services.
- A complex type parameter, not registered in the DI container, is assigned BindingSource.Body.
- A parameter with a name that appears as a route value in ***any*** route template is assigned BindingSource.Path.
- All other parameters are BindingSource.Query.

Disable inference rules

To disable binding source inference, set SuppressInferBindingSourcesForParameters to `true`:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
        options.DisableImplicitFromServicesParameters = true;
    });
```

```
var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Multipart/form-data request inference

The `[ApiController]` attribute applies an inference rule for action parameters of type IFormFile and IFormFileCollection. The `multipart/form-data` request content type is inferred for these types.

To disable the default behavior, set the SuppressConsumesConstraintForFormFileParameters property to `true`:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Problem details for error status codes

MVC transforms an error result (a result with status code 400 or higher) to a result with ProblemDetails. The `ProblemDetails` type is based on the RFC 7807 specification for providing machine-readable error details in an HTTP response.

Consider the following code in a controller action:

C#

```
if (pet == null)
{
    return NotFound();
}
```

The `NotFound` method produces an HTTP 404 status code with a `ProblemDetails` body. For example:

JSON

```
{
  type: "https://tools.ietf.org/html/rfc7231#section-6.5.4",
  title: "Not Found",
  status: 404,
  traceId: "0HLHLV31KRN83:00000001"
}
```

Disable ProblemDetails response

The automatic creation of a `ProblemDetails` for error status codes is disabled when the SuppressMapClientErrors property is set to `true`. Add the following code:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressConsumesConstraintForFormFileParameters = true;
        options.SuppressInferBindingSourcesForParameters = true;
        options.SuppressModelStateInvalidFilter = true;
        options.SuppressMapClientErrors = true;
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
```

```
    });

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Define supported request content types with the [Consumes] attribute

By default, an action supports all available request content types. For example, if an app is configured to support both JSON and XML input formatters, an action supports multiple content types, including `application/json` and `application/xml`.

The [Consumes] attribute allows an action to limit the supported request content types. Apply the `[Consumes]` attribute to an action or controller, specifying one or more content types:

C#

```
[HttpPost]
[Consumes("application/xml")]
public IActionResult CreateProduct(Product product)
```

In the preceding code, the `CreateProduct` action specifies the content type `application/xml`. Requests routed to this action must specify a `Content-Type` header of `application/xml`. Requests that don't specify a `Content-Type` header of `application/xml` result in a 415 Unsupported Media Type response.

The `[Consumes]` attribute also allows an action to influence its selection based on an incoming request's content type by applying a type constraint. Consider the following example:

C#

```
[ApiController]
[Route("api/[controller]")]
public class ConsumesController : ControllerBase
{
    [HttpPost]
```

```
    [Consumes("application/json")]
    public IActionResult PostJson(IEnumerable<int> values) =>
        Ok(new { Consumes = "application/json", Values = values });

    [HttpPost]
    [Consumes("application/x-www-form-urlencoded")]
    public IActionResult PostForm([FromForm] IEnumerable<int> values) =>
        Ok(new { Consumes = "application/x-www-form-urlencoded", Values =
values });
}
```

In the preceding code, `ConsumesController` is configured to handle requests sent to the `https://localhost:5001/api/Consumes` URL. Both of the controller's actions, `PostJson` and `PostForm`, handle POST requests with the same URL. Without the `[Consumes]` attribute applying a type constraint, an ambiguous match exception is thrown.

The `[Consumes]` attribute is applied to both actions. The `PostJson` action handles requests sent with a `Content-Type` header of `application/json`. The `PostForm` action handles requests sent with a `Content-Type` header of `application/x-www-form-urlencoded`.

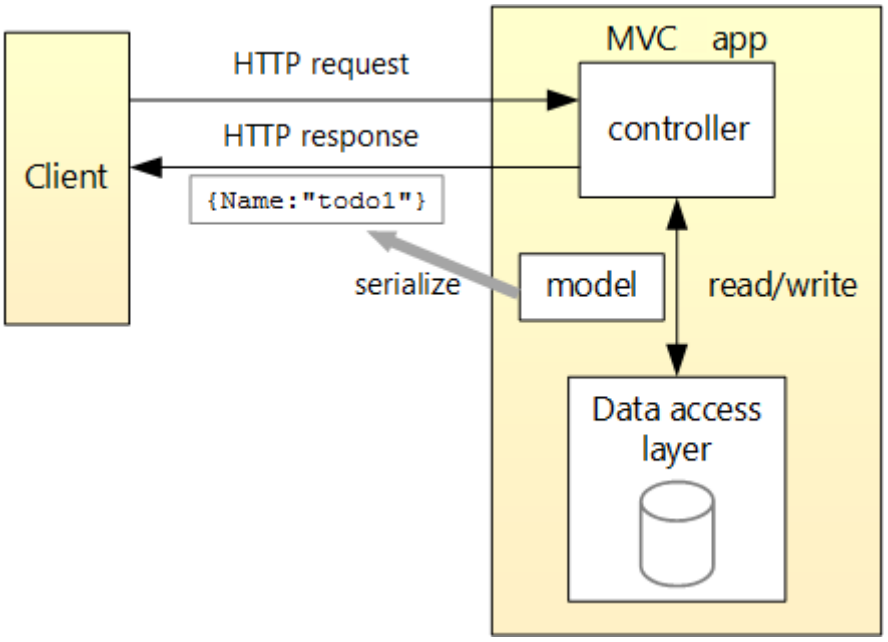
Tutorial: Create a web API with ASP.NET Core

Article • 08/23/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Rick Anderson and Kirk Larkin

This tutorial teaches the basics of building a controller-based web API that uses a database. Another approach to creating APIs in ASP.NET Core is to create *minimal APIs*. For help with choosing between minimal APIs and controller-based APIs, see APIs overview. For a tutorial on creating a minimal API, see Tutorial: Create a minimal API with ASP.NET Core.

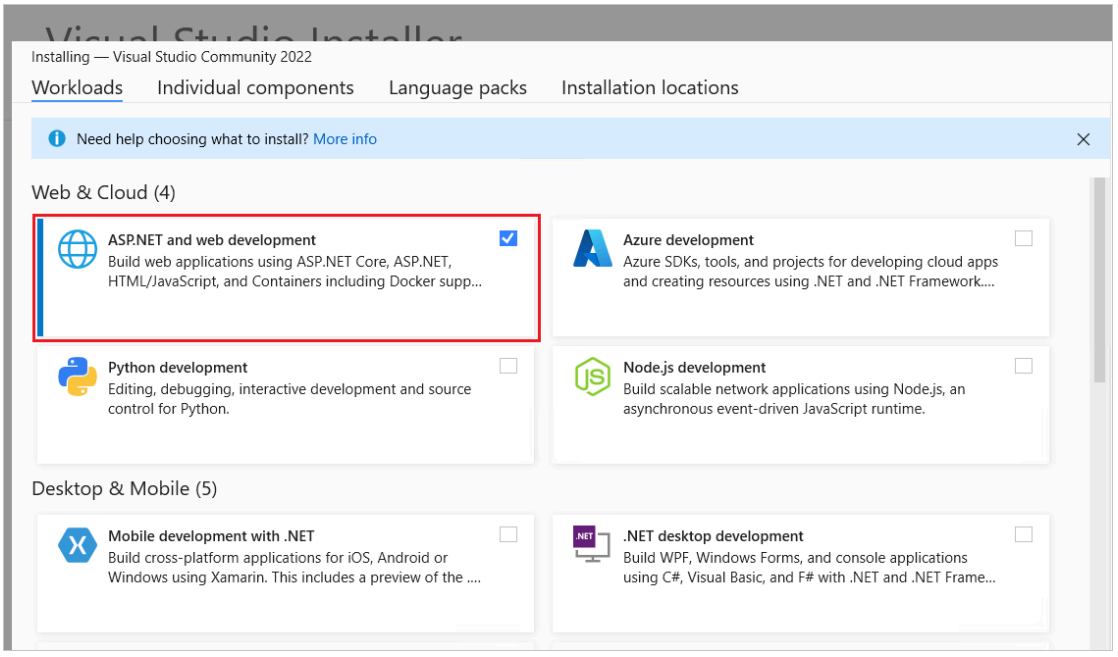


Overview

This tutorial creates the following API:

Expand table

API	Description	Request body	Response body
`GET /api/todoitems`	Get all to-do items	None	Array of to-do items
`GET /api/todoitems/{id}`	Get an item by ID	None	To-do item
`POST /api/todoitems`	Add a new item	To-do item	To-do item
`PUT /api/todoitems/{id}`	Update an existing item	To-do item	None
`DELETE /api/todoitems/{id}`	Delete an item	None	None



The following diagram shows the design of the app.

Prerequisites

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Create a web project

Visual Studio

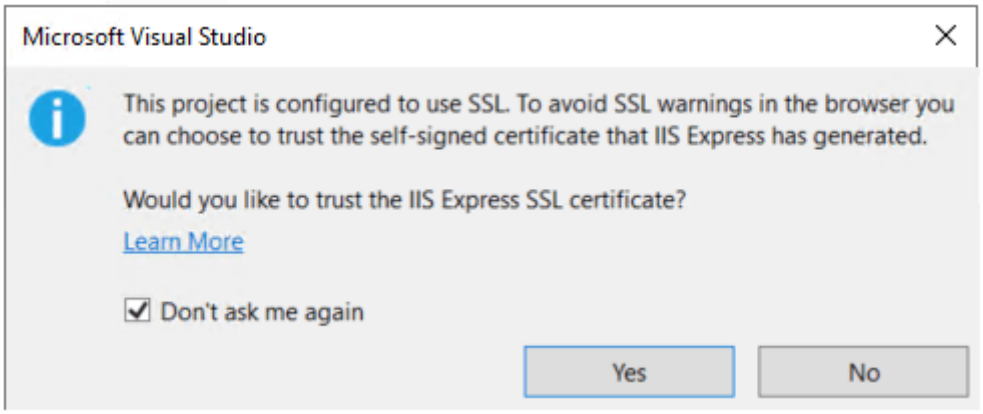
- From the **File** menu, select **New** > **Project**.
- Enter *Web API* in the search box.
- Select the **ASP.NET Core Web API** template and select **Next**.
- In the **Configure your new project dialog**, name the project *TodoApi* and select **Next**.
- In the **Additional information** dialog:
  - Confirm the **Framework** is **.NET 8.0 (Long Term Support)**.
  - Confirm the checkbox for **Use controllers(uncheck to use minimal APIs)** is checked.
  - Confirm the checkbox for **Enable OpenAPI support** is checked.
  - Select **Create**.

Add a NuGet package

A NuGet package must be added to support the database used in this tutorial.

- From the **Tools** menu, select **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
- Select the **Browse** tab.
- Enter **Microsoft.EntityFrameworkCore.InMemory** in the search box, and then select `Microsoft.EntityFrameworkCore.InMemory`.
- Select the **Project** checkbox in the right pane and then select **Install**.

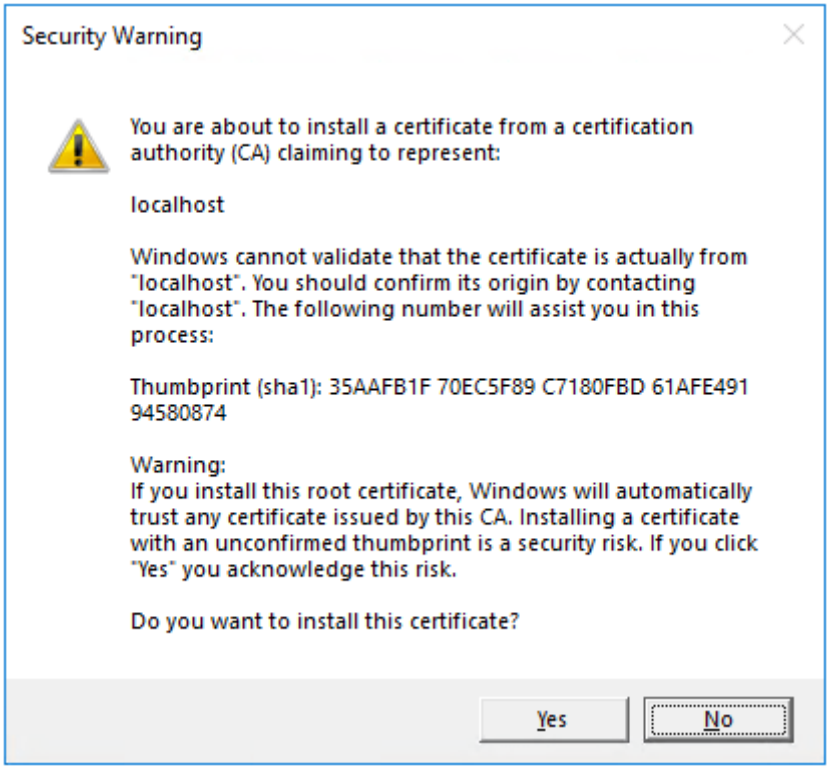
> **Note**
>
> For guidance on adding packages to .NET apps, see the articles under *Install and manage packages* at Package consumption workflow (NuGet documentation). Confirm correct package versions at NuGet.org.



Test the project

The project template creates a `WeatherForecast` API with support for Swagger.

Visual Studio



Press Ctrl+F5 to run without the debugger.

Visual Studio displays the following dialog when a project is not yet configured to use SSL:

Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio launches the default browser and navigates to `https://localhost:<port>/swagger/index.html`, where `<port>` is a randomly chosen port number set at the project creation.

The Swagger page `/swagger/index.html` is displayed. Select **GET** > **Try it out** > **Execute**. The page displays:

- The Curl command to test the WeatherForecast API.
- The URL to test the WeatherForecast API.
- The response code, body, and headers.
- A drop-down list box with media types and the example value and schema.

If the Swagger page doesn't appear, see this GitHub issue.

Swagger is used to generate useful documentation and help pages for web APIs. This tutorial uses Swagger to test the app. For more information on Swagger, see ASP.NET Core web API documentation with Swagger / OpenAPI.

Copy and paste the **Request URL** in the browser: `https://localhost:<port>/weatherforecast`

JSON similar to the following example is returned:

JSON

```
[
    {
        "date": "2019-07-16T19:04:05.7257911-06:00",
        "temperatureC": 52,
        "temperatureF": 125,
        "summary": "Mild"
    },
    {
        "date": "2019-07-17T19:04:05.7258461-06:00",
        "temperatureC": 36,
        "temperatureF": 96,
        "summary": "Warm"
    },
    {
        "date": "2019-07-18T19:04:05.7258467-06:00",
        "temperatureC": 39,
        "temperatureF": 102,
        "summary": "Cool"
    },
    {
        "date": "2019-07-19T19:04:05.7258471-06:00",
        "temperatureC": 10,
        "temperatureF": 49,
        "summary": "Bracing"
    },
    {
        "date": "2019-07-20T19:04:05.7258474-06:00",
        "temperatureC": -1,
        "temperatureF": 31,
```

```
        "summary": "Chilly"
    }
]
```

Add a model class

A *model* is a set of classes that represent the data that the app manages. The model for this app is the `TodoItem` class.

Visual Studio

- In **Solution Explorer**, right-click the project. Select **Add** > **New Folder**. Name the folder `Models`.
- Right-click the `Models` folder and select **Add** > **Class**. Name the class *TodoItem* and select **Add**.
- Replace the template code with the following:

C#

```
namespace TodoApi.Models;

public class TodoItem
{
    public long Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
```

The `Id` property functions as the unique key in a relational database.

Model classes can go anywhere in the project, but the `Models` folder is used by convention.

Add a database context

The *database context* is the main class that coordinates Entity Framework functionality for a data model. This class is created by deriving from the Microsoft.EntityFrameworkCore.DbContext class.

Visual Studio

- Right-click the `Models` folder and select **Add** > **Class**. Name the class *TodoContext* and click **Add**.

- Enter the following code:

```
C#

using Microsoft.EntityFrameworkCore;

namespace TodoApi.Models;

public class TodoContext : DbContext
{
    public TodoContext(DbContextOptions<TodoContext> options)
        : base(options)
    {
    }

    public DbSet<TodoItem> TodoItems { get; set; } = null!;
}
```

Register the database context

In ASP.NET Core, services such as the DB context must be registered with the dependency injection (DI) container. The container provides the service to controllers.

Update `Program.cs` with the following highlighted code:

```
C#

using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddDbContext<TodoContext>(opt =>
    opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddEndpointsApiExplorer();
builder.Services.AddSwaggerGen();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.UseSwagger();
    app.UseSwaggerUI();
```

```
}

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The preceding code:

- Adds `using` directives.
- Adds the database context to the DI container.
- Specifies that the database context will use an in-memory database.

Scaffold a controller

Visual Studio

- Right-click the `Controllers` folder.
- Select **Add** > **New Scaffolded Item**.
- Select **API Controller with actions, using Entity Framework**, and then select **Add**.
- In the **Add API Controller with actions, using Entity Framework** dialog:
  - Select **TodoItem (TodoApi.Models)** in the **Model class**.
  - Select **TodoContext (TodoApi.Models)** in the **Data context class**.
  - Select **Add**.

  If the scaffolding operation fails, select **Add** to try scaffolding a second time.

The generated code:

- Marks the class with the [ApiController] attribute. This attribute indicates that the controller responds to web API requests. For information about specific behaviors that the attribute enables, see Create web APIs with ASP.NET Core.
- Uses DI to inject the database context (`TodoContext`) into the controller. The database context is used in each of the CRUD methods in the controller.

The ASP.NET Core templates for:

- Controllers with views include `[action]` in the route template.
- API controllers don't include `[action]` in the route template.

When the `[action]` token isn't in the route template, the action name (method name) isn't included in the endpoint. That is, the action's associated method name isn't used in the matching route.

Update the PostTodoItem create method

Update the return statement in the `PostTodoItem` to use the nameof operator:

C#

```
[HttpPost]
public async Task<ActionResult<TodoItem>> PostTodoItem(TodoItem todoItem)
{
    _context.TodoItems.Add(todoItem);
    await _context.SaveChangesAsync();

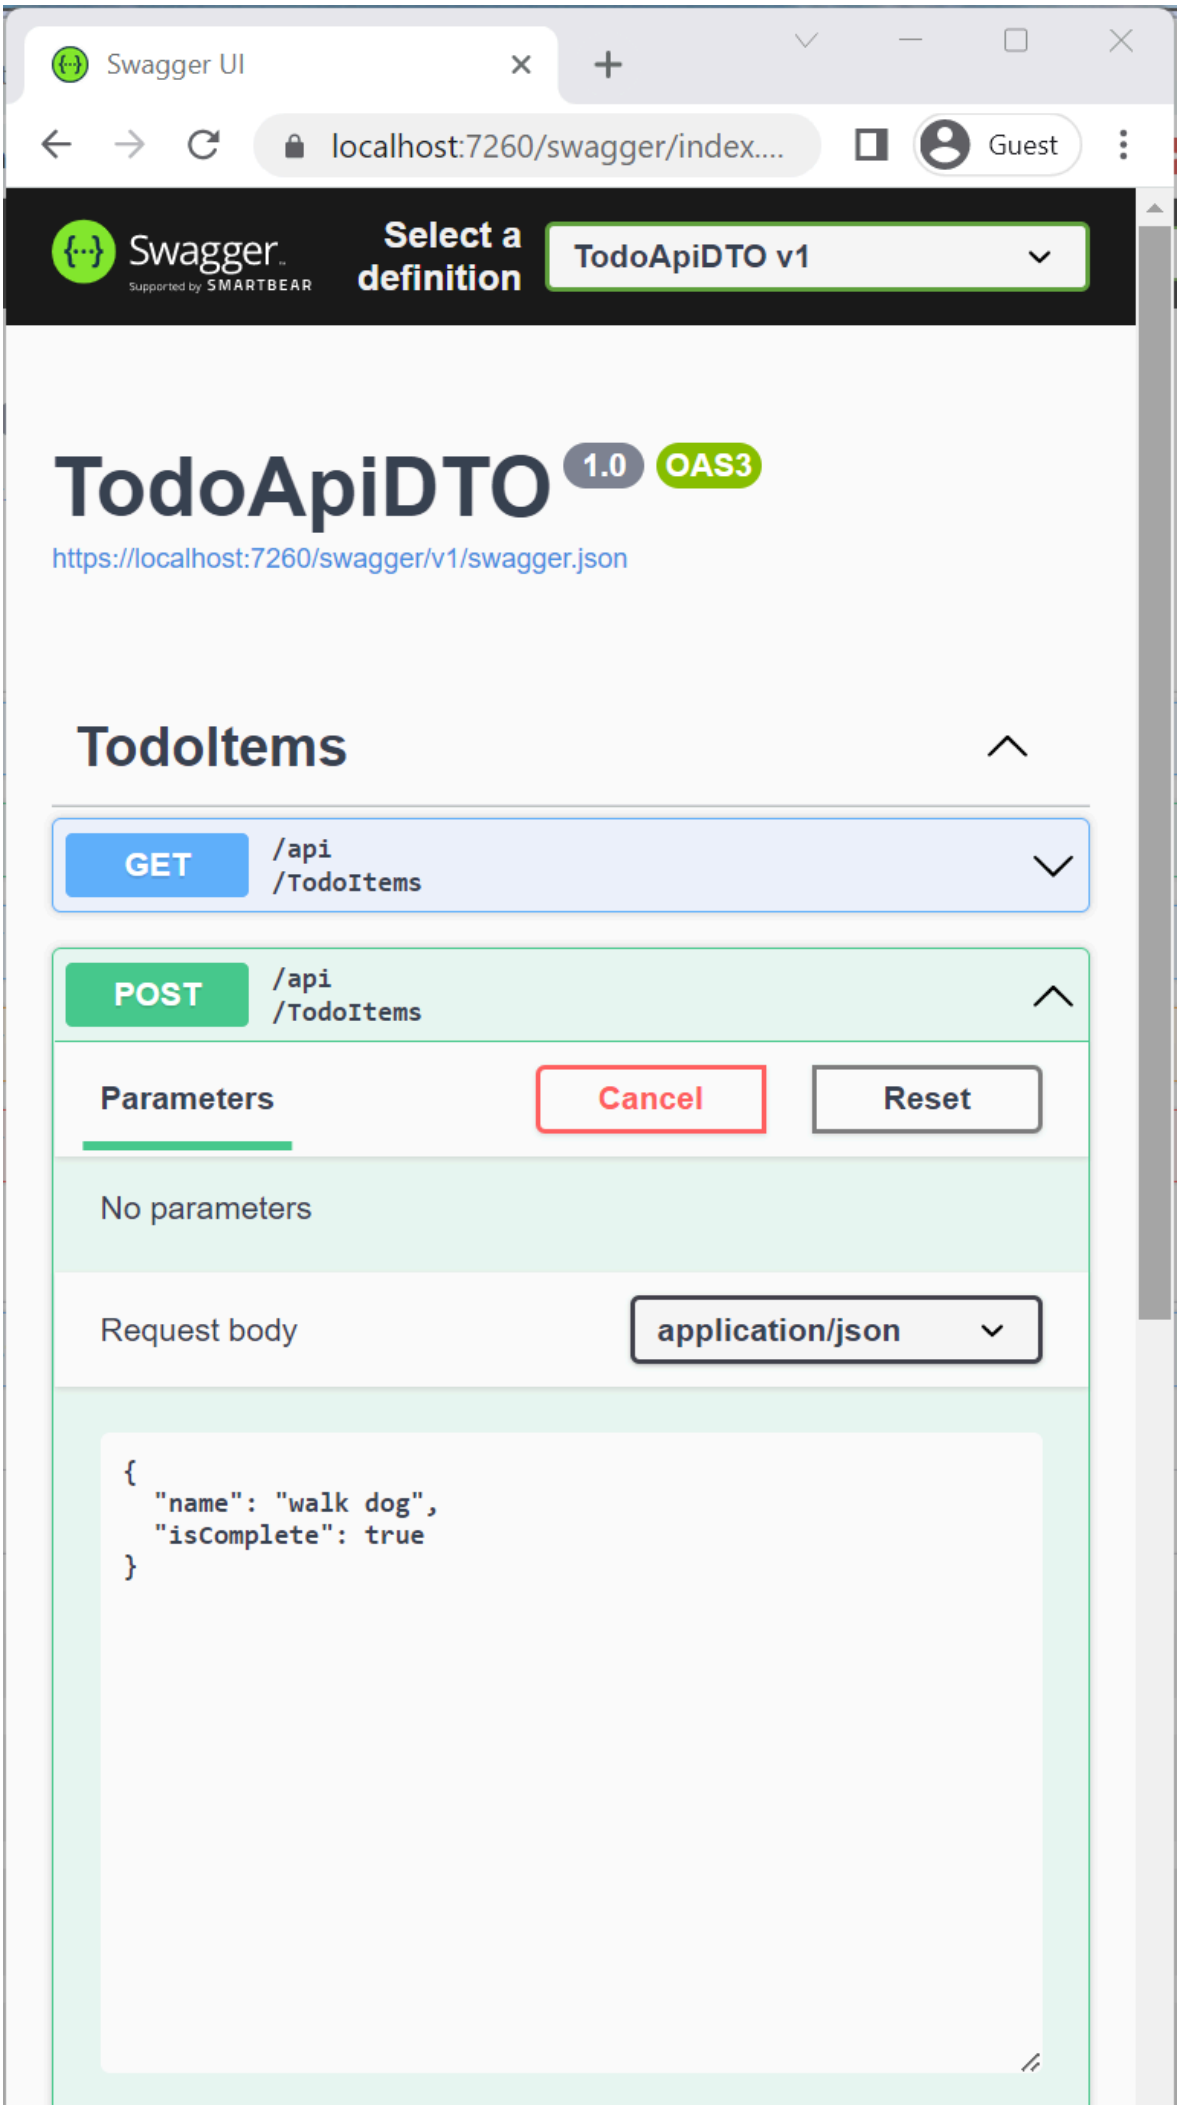
    //    return CreatedAtAction("GetTodoItem", new { id = todoItem.Id },
todoItem);
    return CreatedAtAction(nameof(GetTodoItem), new { id = todoItem.Id },
todoItem);
}
```

The preceding code is an `HTTP POST` method, as indicated by the [HttpPost] attribute. The method gets the value of the `TodoItem` from the body of the HTTP request.

For more information, see Attribute routing with Http[Verb] attributes.

The CreatedAtAction method:

- Returns an HTTP 201 status code if successful. `HTTP 201` is the standard response for an `HTTP POST` method that creates a new resource on the server.
- Adds a Location header to the response. The `Location` header specifies the URI of the newly created to-do item. For more information, see 10.2.2 201 Created.
- References the `GetTodoItem` action to create the `Location` header's URI. The C# `nameof` keyword is used to avoid hard-coding the action name in the `CreatedAtAction` call.



Test PostTodoItem

- Press Ctrl+F5 to run the app.

- In the Swagger browser window, select **POST /api/TodoItems**, and then select **Try it out**.
- In the **Request body** input window, update the JSON. For example,

```JSON
{
  "name": "walk dog",
  "isComplete": true
}
```

- Select **Execute**

Swagger UI
localhost:7260/swagger/index....
Guest

/api
/TodoItems
POST
/api
/TodoItems
Parameters
Cancel
Reset
No parameters
Request body
application/json
{
"name": "walk dog",
"isComplete": true
}

Test the location header URI

In the preceding POST, the Swagger UI shows the location header under **Response headers**. For example, `location: https://localhost:7260/api/TodoItems/1`. The location header shows the URI to the created resource.

To test the location header:

- In the Swagger browser window, select **GET /api/TodoItems/{id}**, and then select **Try it out**.
- Enter `1` in the `id` input box, and then select **Execute**.

GET /api/TodoItems/{id}

Parameters Cancel

Name	Description
id * required integer($int64) (path)	1

Execute Clear

Responses

Curl

```
curl -X 'GET' \
  'https://localhost:7260/api/TodoItems/1' \
  -H 'accept: text/plain'
```

Request URL

```
https://localhost:7260/api/TodoItems/1
```

Server response

Code	Details
200	Response body `{ "id": 1, "name": "walk dog", "isComplete": true }` Download Response headers `content-type: application/json; charset=utf-8` `date: Fri,21 Oct 2022 00:32:45 GMT` `server: Kestrel`

Responses

Code	Description	Links
200	Success Media type: text/plain Controls Accept header. Example Value | Schema `{ "id": 0, "name": "string", "isComplete": true }`	*No links*

Examine the GET methods

Two GET endpoints are implemented:

- `GET /api/todoitems`
- `GET /api/todoitems/{id}`

The previous section showed an example of the `/api/todoitems/{id}` route.

Follow the POST instructions to add another todo item, and then test the `/api/todoitems` route using Swagger.

This app uses an in-memory database. If the app is stopped and started, the preceding GET request doesn't return any data. If no data is returned, POST data to the app.

Routing and URL paths

The [HttpGet] attribute denotes a method that responds to an `HTTP GET` request. The URL path for each method is constructed as follows:

- Start with the template string in the controller's `Route` attribute:

```
C#

[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
```

- Replace `[controller]` with the name of the controller, which by convention is the controller class name minus the "Controller" suffix. For this sample, the controller class name is **TodoItems**Controller, so the controller name is "TodoItems". ASP.NET Core routing is case insensitive.

- If the `[HttpGet]` attribute has a route template (for example, `[HttpGet("products")]`), append that to the path. This sample doesn't use a template. For more information, see Attribute routing with Http[Verb] attributes.

In the following `GetTodoItem` method, `"{id}"` is a placeholder variable for the unique identifier of the to-do item. When `GetTodoItem` is invoked, the value of `"{id}"` in the URL is provided to the method in its `id` parameter.

C#

```
[HttpGet("{id}")]
public async Task<ActionResult<TodoItem>> GetTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);

    if (todoItem == null)
    {
        return NotFound();
    }

    return todoItem;
}
```

Return values

The return type of the `GetTodoItems` and `GetTodoItem` methods is ActionResult<T> type. ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200 OK, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

`ActionResult` return types can represent a wide range of HTTP status codes. For example, `GetTodoItem` can return two different status values:

- If no item matches the requested ID, the method returns a 404 status NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an `HTTP 200` response.

The PutTodoItem method

Examine the `PutTodoItem` method:

C#

```
[HttpPut("{id}")]
public async Task<IActionResult> PutTodoItem(long id, TodoItem todoItem)
{
    if (id != todoItem.Id)
    {
        return BadRequest();
    }

    _context.Entry(todoItem).State = EntityState.Modified;
```

```
    try
    {
        await _context.SaveChangesAsync();
    }
    catch (DbUpdateConcurrencyException)
    {
        if (!TodoItemExists(id))
        {
            return NotFound();
        }
        else
        {
            throw;
        }
    }

    return NoContent();
}
```

`PutTodoItem` is similar to `PostTodoItem`, except it uses `HTTP PUT`. The response is 204 (No Content). According to the HTTP specification, a `PUT` request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

Test the PutTodoItem method

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Using the Swagger UI, use the PUT button to update the `TodoItem` that has Id = 1 and set its name to `"feed fish"`. Note the response is HTTP 204 No Content.

The DeleteTodoItem method

Examine the `DeleteTodoItem` method:

C#

```
[HttpDelete("{id}")]
public async Task<IActionResult> DeleteTodoItem(long id)
{
    var todoItem = await _context.TodoItems.FindAsync(id);
    if (todoItem == null)
    {
        return NotFound();
```

```
    }

    _context.TodoItems.Remove(todoItem);
    await _context.SaveChangesAsync();

    return NoContent();
}
```

Test the DeleteTodoItem method

Use the Swagger UI to delete the `TodoItem` that has Id = 1. Note the response is HTTP 204 No Content.

Test with other tools

There are many other tools that can be used to test web APIs, for example:

- Visual Studio Endpoints Explorer and .http files
- http-repl
- curl. Swagger uses `curl` and shows the `curl` commands it submits.
- Fiddler

For more information, see:

- Minimal API tutorial: test with .http files and Endpoints Explorer
- Install and test APIs with http-repl

Prevent over-posting

Currently the sample app exposes the entire `TodoItem` object. Production apps typically limit the data that's input and returned using a subset of the model. There are multiple reasons behind this, and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this tutorial.

A DTO may be used to:

- Prevent over-posting.
- Hide properties that clients are not supposed to view.
- Omit some properties in order to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `TodoItem` class to include a secret field:

C#

```
namespace TodoApi.Models
{
    public class TodoItem
    {
        public long Id { get; set; }
        public string? Name { get; set; }
        public bool IsComplete { get; set; }
        public string? Secret { get; set; }
    }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a DTO model:

C#

```
namespace TodoApi.Models;

public class TodoItemDTO
{
    public long Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
```

Update the `TodoItemsController` to use `TodoItemDTO`:

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

namespace TodoApi.Controllers;

[Route("api/[controller]")]
[ApiController]
public class TodoItemsController : ControllerBase
{
    private readonly TodoContext _context;

    public TodoItemsController(TodoContext context)
```

```
    {
        _context = context;
    }

    // GET: api/TodoItems
    [HttpGet]
    public async Task<ActionResult<IEnumerable<TodoItemDTO>>> GetTodoItems()
    {
        return await _context.TodoItems
            .Select(x => ItemToDTO(x))
            .ToListAsync();
    }

    // GET: api/TodoItems/5
    // <snippet_GetByID>
    [HttpGet("{id}")]
    public async Task<ActionResult<TodoItemDTO>> GetTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);

        if (todoItem == null)
        {
            return NotFound();
        }

        return ItemToDTO(todoItem);
    }
    // </snippet_GetByID>

    // PUT: api/TodoItems/5
    // To protect from overposting attacks, see
https://go.microsoft.com/fwlink/?linkid=2123754
    // <snippet_Update>
    [HttpPut("{id}")]
    public async Task<IActionResult> PutTodoItem(long id, TodoItemDTO
todoDTO)
    {
        if (id != todoDTO.Id)
        {
            return BadRequest();
        }

        var todoItem = await _context.TodoItems.FindAsync(id);
        if (todoItem == null)
        {
            return NotFound();
        }

        todoItem.Name = todoDTO.Name;
        todoItem.IsComplete = todoDTO.IsComplete;

        try
        {
            await _context.SaveChangesAsync();
        }
```

```
        catch (DbUpdateConcurrencyException) when (!TodoItemExists(id))
        {
            return NotFound();
        }

        return NoContent();
    }
    // </snippet_Update>

    // POST: api/TodoItems
    // To protect from overposting attacks, see
https://go.microsoft.com/fwlink/?linkid=2123754
    // <snippet_Create>
    [HttpPost]
    public async Task<ActionResult<TodoItemDTO>> PostTodoItem(TodoItemDTO
todoDTO)
    {
        var todoItem = new TodoItem
        {
            IsComplete = todoDTO.IsComplete,
            Name = todoDTO.Name
        };

        _context.TodoItems.Add(todoItem);
        await _context.SaveChangesAsync();

        return CreatedAtAction(
            nameof(GetTodoItem),
            new { id = todoItem.Id },
            ItemToDTO(todoItem));
    }
    // </snippet_Create>

    // DELETE: api/TodoItems/5
    [HttpDelete("{id}")]
    public async Task<IActionResult> DeleteTodoItem(long id)
    {
        var todoItem = await _context.TodoItems.FindAsync(id);
        if (todoItem == null)
        {
            return NotFound();
        }

        _context.TodoItems.Remove(todoItem);
        await _context.SaveChangesAsync();

        return NoContent();
    }

    private bool TodoItemExists(long id)
    {
        return _context.TodoItems.Any(e => e.Id == id);
    }

    private static TodoItemDTO ItemToDTO(TodoItem todoItem) =>
```

```
        new TodoItemDTO
        {
            Id = todoItem.Id,
            Name = todoItem.Name,
            IsComplete = todoItem.IsComplete
        };
}
```

Verify you can't post or get the secret field.

Call the web API with JavaScript

See Tutorial: Call an ASP.NET Core web API with JavaScript.

Web API video series

See Video: Beginner's Series to: Web APIs.

Reliable web app patterns

See *The Reliable Web App Pattern for.NET* YouTube videos and article for guidance on creating a modern, reliable, performant, testable, cost-efficient, and scalable ASP.NET Core app, whether from scratch or refactoring an existing app.

Add authentication support to a web API

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Microsoft Entra ID
- Azure Active Directory B2C (Azure AD B2C)
- Duende Identity Server

Duende Identity Server is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. Duende Identity Server enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

> **Important**
>
> Duende Software might require you to pay a license fee for production use of Duende Identity Server. For more information, see **Migrate from ASP.NET Core 5.0 to 6.0**.

For more information, see the Duende Identity Server documentation (Duende Software website).

Publish to Azure

For information on deploying to Azure, see Quickstart: Deploy an ASP.NET web app.

>
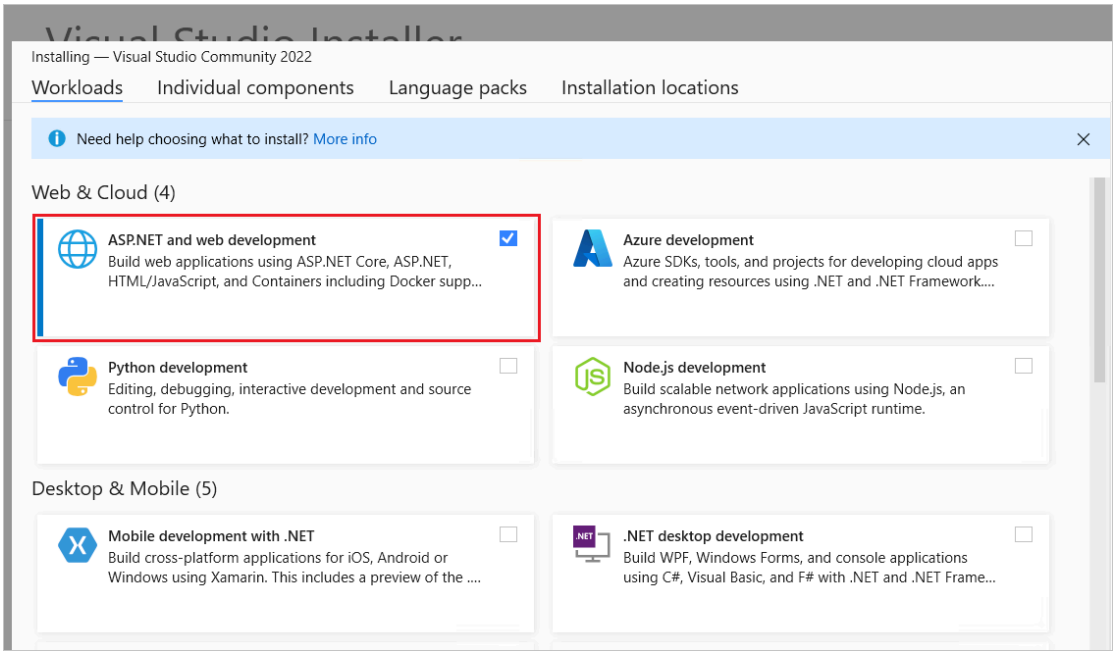
> For the current release, see the .NET 8 version of this article.

By Pratik Khandelwal and Scott Addie

This tutorial creates a web API that runs Create, Read, Update, and Delete (CRUD) operations on a MongoDB NoSQL database.

In this tutorial, you learn how to:



- ✓ Configure MongoDB
- ✓ Create a MongoDB database
- ✓ Define a MongoDB collection and schema
- ✓ Perform MongoDB CRUD operations from a web API
- ✓ Customize JSON serialization

Prerequisites

- MongoDB 6.0.5 or later
- MongoDB Shell

Visual Studio

- Visual Studio 2022 with the **ASP.NET and web development** workload.

Configure MongoDB

Enable MongoDB and MongoDB Shell access from anywhere on the development machine (Windows/Linux/macOS):

1. Download and Install MongoDB Shell:

    - macOS/Linux: Choose a directory to extract the MongoDB Shell to. Add the resulting path for `mongosh` to the `PATH` environment variable.
    - Windows: MongoDB Shell (mongosh.exe) is installed at *C:\Users<user>\AppData\Local\Programs\mongosh*. Add the resulting path for `mongosh.exe` to the `PATH` environment variable.

2. Download and Install MongoDB:

    - macOS/Linux: Verify the directory that MongoDB was installed at, usually in */usr/local/mongodb*. Add the resulting path for `mongodb` to the `PATH` environment variable.
    - Windows: MongoDB is installed at *C:\Program Files\MongoDB* by default. Add *C:\Program Files\MongoDB\Server\<version_number>\bin* to the `PATH` environment variable.

3. Choose a Data Storage Directory: Select a directory on your development machine for storing data. Create the directory if it doesn't exist. The MongoDB Shell doesn't create new directories:

    - macOS/Linux: For example, `/usr/local/var/mongodb`.

- Windows: For example, `C:\\BooksData`.

4. In the OS command shell (not the MongoDB Shell), use the following command to connect to MongoDB on default port 27017. Replace `<data_directory_path>` with the directory chosen in the previous step.

```
Console

mongod --dbpath <data_directory_path>
```

Use the previously installed MongoDB Shell in the following steps to create a database, make collections, and store documents. For more information on MongoDB Shell commands, see mongosh.

1. Open a MongoDB command shell instance by launching `mongosh.exe`.

2. In the command shell, connect to the default test database by running the following command:

```
Console

mongosh
```

3. Run the following command in the command shell:

```
Console

use BookStore
```

   A database named *BookStore* is created if it doesn't already exist. If the database does exist, its connection is opened for transactions.

4. Create a `Books` collection using following command:

```
Console

db.createCollection('Books')
```

   The following result is displayed:

```
Console

{ "ok" : 1 }
```

5. Define a schema for the `Books` collection and insert two documents using the following command:

```
Console

db.Books.insertMany([{ "Name": "Design Patterns", "Price": 54.93,
"Category": "Computers", "Author": "Ralph Johnson" }, { "Name": "Clean
Code", "Price": 43.15, "Category": "Computers","Author": "Robert C.
Martin" }])
```

A result similar to the following is displayed:

```
Console

{
    "acknowledged" : true,
    "insertedIds" : [
        ObjectId("61a6058e6c43f32854e51f51"),
        ObjectId("61a6058e6c43f32854e51f52")
    ]
}
```

> **Note**
>
> The `ObjectId`s shown in the preceding result won't match those shown in the command shell.

6. View the documents in the database using the following command:

```
Console

db.Books.find().pretty()
```

A result similar to the following is displayed:

```
Console

{
    "_id" : ObjectId("61a6058e6c43f32854e51f51"),
    "Name" : "Design Patterns",
    "Price" : 54.93,
    "Category" : "Computers",
    "Author" : "Ralph Johnson"
}
{
    "_id" : ObjectId("61a6058e6c43f32854e51f52"),
```

```
    "Name" : "Clean Code",
    "Price" : 43.15,
    "Category" : "Computers",
    "Author" : "Robert C. Martin"
}
```

The schema adds an autogenerated `_id` property of type `ObjectId` for each document.

Create the ASP.NET Core web API project

Visual Studio

1. Go to **File** > **New** > **Project**.
2. Select the **ASP.NET Core Web API** project type, and select **Next**.
3. Name the project *BookStoreApi*, and select **Next**.
4. Select the **.NET 8.0 (Long Term support)** framework and select **Create**.
5. In the **Package Manager Console** window, navigate to the project root. Run the following command to install the .NET driver for MongoDB:

PowerShell

```
Install-Package MongoDB.Driver
```

Add an entity model

1. Add a *Models* directory to the project root.
2. Add a `Book` class to the *Models* directory with the following code:

C#

```
using MongoDB.Bson;
using MongoDB.Bson.Serialization.Attributes;

namespace BookStoreApi.Models;

public class Book
{
```

```
    [BsonId]
    [BsonRepresentation(BsonType.ObjectId)]
    public string? Id { get; set; }

    [BsonElement("Name")]
    public string BookName { get; set; } = null!;

    public decimal Price { get; set; }

    public string Category { get; set; } = null!;

    public string Author { get; set; } = null!;
}
```

In the preceding class, the `Id` property is:

- Required for mapping the Common Language Runtime (CLR) object to the MongoDB collection.
- Annotated with [BsonId] to make this property the document's primary key.
- Annotated with [BsonRepresentation(BsonType.ObjectId)] to allow passing the parameter as type `string` instead of an ObjectId structure. Mongo handles the conversion from `string` to `ObjectId`.

The `BookName` property is annotated with the [BsonElement] attribute. The attribute's value of `Name` represents the property name in the MongoDB collection.

Add a configuration model

1. Add the following database configuration values to `appsettings.json`:

JSON

```
{
    "BookStoreDatabase": {
        "ConnectionString": "mongodb://localhost:27017",
        "DatabaseName": "BookStore",
        "BooksCollectionName": "Books"
    },
    "Logging": {
        "LogLevel": {
            "Default": "Information",
            "Microsoft.AspNetCore": "Warning"
        }
    },
    "AllowedHosts": "*"
}
```

2. Add a `BookStoreDatabaseSettings` class to the *Models* directory with the following code:

```C#
namespace BookStoreApi.Models;

public class BookStoreDatabaseSettings
{
    public string ConnectionString { get; set; } = null!;

    public string DatabaseName { get; set; } = null!;

    public string BooksCollectionName { get; set; } = null!;
}
```

   The preceding `BookStoreDatabaseSettings` class is used to store the `appsettings.json` file's `BookStoreDatabase` property values. The JSON and C# property names are named identically to ease the mapping process.

3. Add the following highlighted code to `Program.cs`:

```C#
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.Configure<BookStoreDatabaseSettings>(
    builder.Configuration.GetSection("BookStoreDatabase"));
```

   In the preceding code, the configuration instance to which the `appsettings.json` file's `BookStoreDatabase` section binds is registered in the Dependency Injection (DI) container. For example, the `BookStoreDatabaseSettings` object's `ConnectionString` property is populated with the `BookStoreDatabase:ConnectionString` property in `appsettings.json`.

4. Add the following code to the top of `Program.cs` to resolve the `BookStoreDatabaseSettings` reference:

```C#
using BookStoreApi.Models;
```

Add a CRUD operations service

1. Add a *Services* directory to the project root.

2. Add a `BooksService` class to the *Services* directory with the following code:

C#

```
using BookStoreApi.Models;
using Microsoft.Extensions.Options;
using MongoDB.Driver;

namespace BookStoreApi.Services;

public class BooksService
{
    private readonly IMongoCollection<Book> _booksCollection;

    public BooksService(
        IOptions<BookStoreDatabaseSettings> bookStoreDatabaseSettings)
    {
        var mongoClient = new MongoClient(
            bookStoreDatabaseSettings.Value.ConnectionString);

        var mongoDatabase = mongoClient.GetDatabase(
            bookStoreDatabaseSettings.Value.DatabaseName);

        _booksCollection = mongoDatabase.GetCollection<Book>(
            bookStoreDatabaseSettings.Value.BooksCollectionName);
    }

    public async Task<List<Book>> GetAsync() =>
        await _booksCollection.Find(_ => true).ToListAsync();

    public async Task<Book?> GetAsync(string id) =>
        await _booksCollection.Find(x => x.Id ==
id).FirstOrDefaultAsync();

    public async Task CreateAsync(Book newBook) =>
        await _booksCollection.InsertOneAsync(newBook);

    public async Task UpdateAsync(string id, Book updatedBook) =>
        await _booksCollection.ReplaceOneAsync(x => x.Id == id,
updatedBook);

    public async Task RemoveAsync(string id) =>
        await _booksCollection.DeleteOneAsync(x => x.Id == id);
}
```

In the preceding code, a `BookStoreDatabaseSettings` instance is retrieved from DI via constructor injection. This technique provides access to the `appsettings.json` configuration values that were added in the Add a configuration model section.

3. Add the following highlighted code to `Program.cs`:

```C#
var builder = WebApplication.CreateBuilder(args);

// Add services to the container.
builder.Services.Configure<BookStoreDatabaseSettings>(
    builder.Configuration.GetSection("BookStoreDatabase"));

builder.Services.AddSingleton<BooksService>();
```

In the preceding code, the `BooksService` class is registered with DI to support constructor injection in consuming classes. The singleton service lifetime is most appropriate because `BooksService` takes a direct dependency on `MongoClient`. Per the official Mongo Client reuse guidelines, `MongoClient` should be registered in DI with a singleton service lifetime.

4. Add the following code to the top of `Program.cs` to resolve the `BooksService` reference:

```C#
using BookStoreApi.Services;
```

The `BooksService` class uses the following `MongoDB.Driver` members to run CRUD operations against the database:

- MongoClient: Reads the server instance for running database operations. The constructor of this class is provided in the MongoDB connection string:

```C#
public BooksService(
    IOptions<BookStoreDatabaseSettings> bookStoreDatabaseSettings)
{
    var mongoClient = new MongoClient(
        bookStoreDatabaseSettings.Value.ConnectionString);

    var mongoDatabase = mongoClient.GetDatabase(
        bookStoreDatabaseSettings.Value.DatabaseName);

    _booksCollection = mongoDatabase.GetCollection<Book>(
        bookStoreDatabaseSettings.Value.BooksCollectionName);
}
```

- IMongoDatabase: Represents the Mongo database for running operations. This tutorial uses the generic GetCollection<TDocument>(collection) method on the interface to gain access to data in a specific collection. Run CRUD operations against the collection after this method is called. In the `GetCollection<TDocument>(collection)` method call:
  - `collection` represents the collection name.
  - `TDocument` represents the CLR object type stored in the collection.

`GetCollection<TDocument>(collection)` returns a MongoCollection object representing the collection. In this tutorial, the following methods are invoked on the collection:

- DeleteOneAsync: Deletes a single document matching the provided search criteria.
- Find<TDocument>: Returns all documents in the collection matching the provided search criteria.
- InsertOneAsync: Inserts the provided object as a new document in the collection.
- ReplaceOneAsync: Replaces the single document matching the provided search criteria with the provided object.

Add a controller

Add a `BooksController` class to the *Controllers* directory with the following code:

C#

```
using BookStoreApi.Models;
using BookStoreApi.Services;
using Microsoft.AspNetCore.Mvc;

namespace BookStoreApi.Controllers;

[ApiController]
[Route("api/[controller]")]
public class BooksController : ControllerBase
{
    private readonly BooksService _booksService;

    public BooksController(BooksService booksService) =>
        _booksService = booksService;

    [HttpGet]
    public async Task<List<Book>> Get() =>
        await _booksService.GetAsync();

    [HttpGet("{id:length(24)}")]
```

```
    public async Task<ActionResult<Book>> Get(string id)
    {
        var book = await _booksService.GetAsync(id);

        if (book is null)
        {
            return NotFound();
        }

        return book;
    }

    [HttpPost]
    public async Task<IActionResult> Post(Book newBook)
    {
        await _booksService.CreateAsync(newBook);

        return CreatedAtAction(nameof(Get), new { id = newBook.Id },
newBook);
    }

    [HttpPut("{id:length(24)}")]
    public async Task<IActionResult> Update(string id, Book updatedBook)
    {
        var book = await _booksService.GetAsync(id);

        if (book is null)
        {
            return NotFound();
        }

        updatedBook.Id = book.Id;

        await _booksService.UpdateAsync(id, updatedBook);

        return NoContent();
    }

    [HttpDelete("{id:length(24)}")]
    public async Task<IActionResult> Delete(string id)
    {
        var book = await _booksService.GetAsync(id);

        if (book is null)
        {
            return NotFound();
        }

        await _booksService.RemoveAsync(id);

        return NoContent();
    }
}
```

The preceding web API controller:

- Uses the `BooksService` class to run CRUD operations.
- Contains action methods to support GET, POST, PUT, and DELETE HTTP requests.
- Calls CreatedAtAction in the `Create` action method to return an HTTP 201 response. Status code 201 is the standard response for an HTTP POST method that creates a new resource on the server. `CreatedAtAction` also adds a `Location` header to the response. The `Location` header specifies the URI of the newly created book.

Test the web API

1. Build and run the app.

2. Navigate to `https://localhost:<port>/api/books`, where `<port>` is the automatically assigned port number for the app, to test the controller's parameterless `Get` action method, select **Try it out** > **Execute**. A JSON response similar to the following is displayed:

   JSON

   ```
   [
     {
       "id": "61a6058e6c43f32854e51f51",
       "bookName": "Design Patterns",
       "price": 54.93,
       "category": "Computers",
       "author": "Ralph Johnson"
     },
     {
       "id": "61a6058e6c43f32854e51f52",
       "bookName": "Clean Code",
       "price": 43.15,
       "category": "Computers",
       "author": "Robert C. Martin"
     }
   ]
   ```

3. Navigate to `https://localhost:<port>/api/books/{id here}` to test the controller's overloaded `Get` action method. A JSON response similar to the following is displayed:

   JSON

   ```
   {
     "id": "61a6058e6c43f32854e51f52",
   ```

```
  "bookName": "Clean Code",
  "price": 43.15,
  "category": "Computers",
  "author": "Robert C. Martin"
}
```

Configure JSON serialization options

There are two details to change about the JSON responses returned in the Test the web API section:

- The property names' default camel casing should be changed to match the Pascal casing of the CLR object's property names.
- The `bookName` property should be returned as `Name`.

To satisfy the preceding requirements, make the following changes:

1. In `Program.cs`, chain the following highlighted code on to the `AddControllers` method call:

   C#

   ```
   var builder = WebApplication.CreateBuilder(args);

   // Add services to the container.
   builder.Services.Configure<BookStoreDatabaseSettings>(
       builder.Configuration.GetSection("BookStoreDatabase"));

   builder.Services.AddSingleton<BooksService>();

   builder.Services.AddControllers()
       .AddJsonOptions(
           options => options.JsonSerializerOptions.PropertyNamingPolicy =
   null);
   ```

   With the preceding change, property names in the web API's serialized JSON response match their corresponding property names in the CLR object type. For example, the `Book` class's `Author` property serializes as `Author` instead of `author`.

2. In `Models/Book.cs`, annotate the `BookName` property with the [JsonPropertyName] attribute:

   C#

   ```
   [BsonElement("Name")]
   [JsonPropertyName("Name")]
   ```

```
public string BookName { get; set; } = null!;
```

The `[JsonPropertyName]` attribute's value of `Name` represents the property name in the web API's serialized JSON response.

3. Add the following code to the top of `Models/Book.cs` to resolve the `[JsonProperty]` attribute reference:

```
C#

using System.Text.Json.Serialization;
```

4. Repeat the steps defined in the Test the web API section. Notice the difference in JSON property names.

Add authentication support to a web API

ASP.NET Core Identity adds user interface (UI) login functionality to ASP.NET Core web apps. To secure web APIs and SPAs, use one of the following:

- Microsoft Entra ID
- Azure Active Directory B2C (Azure AD B2C)
- Duende Identity Server

Duende Identity Server is an OpenID Connect and OAuth 2.0 framework for ASP.NET Core. Duende Identity Server enables the following security features:

- Authentication as a Service (AaaS)
- Single sign-on/off (SSO) over multiple application types
- Access control for APIs
- Federation Gateway

> **Important**
>
> Duende Software might require you to pay a license fee for production use of Duende Identity Server. For more information, see Migrate from ASP.NET Core 5.0 to 6.0.

For more information, see the Duende Identity Server documentation (Duende Software website).

Controller action return types in ASP.NET Core web API

Article • 09/28/2023

View or download sample code (how to download)

ASP.NET Core provides the following options for web API controller action return types:

- Specific type
- IActionResult
- ActionResult<T>
- HttpResults

This article explains when it's most appropriate to use each return type.

Specific type

The most basic action returns a primitive or complex data type, for example, `string` or a custom object. Consider the following action, which returns a collection of custom `Product` objects:

```
C#
```

```
[HttpGet]
public Task<List<Product>> Get() =>
    _productContext.Products.OrderBy(p => p.Name).ToListAsync();
```

Without known conditions to safeguard against, returning a specific type could suffice. The preceding action accepts no parameters, so parameter constraints validation isn't needed.

When multiple return types are possible, it's common to mix an ActionResult return type with the primitive or complex return type. Either IActionResult or ActionResult<T> are necessary to accommodate this type of action. Several samples of multiple return types are provided in this article.

Return IEnumerable<T> or IAsyncEnumerable<T>

See Return IEnumerable<T> or IAsyncEnumerable<T> for performance considerations.

ASP.NET Core buffers the result of actions that return IEnumerable<T> before writing them to the response. Consider declaring the action signature's return type as IAsyncEnumerable<T> to guarantee asynchronous iteration. Ultimately, the iteration mode is based on the underlying concrete type being returned and the selected formatter affects how the result is processed:

- When using `System.Text.Json` formatter, MVC relies on the support that `System.Text.Json` added to **stream** the result.
- When using `Newtonsoft.Json` or with `XML-based` formatters the result is buffered.

Consider the following action, which returns sale-priced product records as `IEnumerable<Product>`:

C#

```
[HttpGet("syncsale")]
public IEnumerable<Product> GetOnSaleProducts()
{
    var products = _productContext.Products.OrderBy(p => p.Name).ToList();

    foreach (var product in products)
    {
        if (product.IsOnSale)
        {
            yield return product;
        }
    }
}
```

The `IAsyncEnumerable<Product>` equivalent of the preceding action is:

C#

```
[HttpGet("asyncsale")]
public async IAsyncEnumerable<Product> GetOnSaleProductsAsync()
{
    var products = _productContext.Products.OrderBy(p =>
p.Name).AsAsyncEnumerable();

    await foreach (var product in products)
    {
        if (product.IsOnSale)
        {
            yield return product;
        }
    }
}
```

IActionResult type

The IActionResult return type is appropriate when multiple `ActionResult` return types are possible in an action. The `ActionResult` types represent various HTTP status codes. Any non-abstract class deriving from `ActionResult` qualifies as a valid return type. Some common return types in this category are BadRequestResult (400), NotFoundResult (404), and OkObjectResult (200). Alternatively, convenience methods in the ControllerBase class can be used to return `ActionResult` types from an action. For example, `return BadRequest();` is a shorthand form of `return new BadRequestResult();`.

Because there are multiple return types and paths in this type of action, liberal use of the [ProducesResponseType] attribute is necessary. This attribute produces more descriptive response details for web API help pages generated by tools like Swagger. `[ProducesResponseType]` indicates the known types and HTTP status codes to be returned by the action.

Synchronous action

Consider the following synchronous action in which there are two possible return types:

C#

```
[HttpGet("{id}")]
[ProducesResponseType<Product>(StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
public IActionResult GetById_IActionResult(int id)
{
    var product = _productContext.Products.Find(id);
    return product == null ? NotFound() : Ok(product);
}
```

In the preceding action:

- A 404 status code is returned when the product represented by `id` doesn't exist in the underlying data store. The NotFound convenience method is invoked as shorthand for `return new NotFoundResult();`.
- A 200 status code is returned with the `Product` object when the product does exist. The Ok convenience method is invoked as shorthand for `return new OkObjectResult(product);`.

Asynchronous action

Consider the following asynchronous action in which there are two possible return types:

```
C#

[HttpPost()]
[Consumes(MediaTypeNames.Application.Json)]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public async Task<IActionResult> CreateAsync_IActionResult(Product product)
{
    if (product.Description.Contains("XYZ Widget"))
    {
        return BadRequest();
    }

    _productContext.Products.Add(product);
    await _productContext.SaveChangesAsync();

    return CreatedAtAction(nameof(CreateAsync_IActionResult), new { id =
product.Id }, product);
}
```

In the preceding action:

- A 400 status code is returned when the product description contains "XYZ Widget". The BadRequest convenience method is invoked as shorthand for `return new BadRequestResult();`.
- A 201 status code is generated by the CreatedAtAction convenience method when a product is created. The following code is an alternative to calling `CreatedAtAction`:

  ```
  C#

  return new CreatedAtActionResult(nameof(CreateAsync),
                                   "Products",
                                   new { id = product.Id },
                                   product);
  ```

  In the preceding code path, the `Product` object is provided in the response body. A `Location` response header containing the newly created product's URL is provided.

For example, the following model indicates that requests must include the `Name` and `Description` properties. Failure to provide `Name` and `Description` in the request causes model validation to fail.

C#

```
public class Product
{
    public int Id { get; set; }

    [Required]
    public string Name { get; set; } = string.Empty;

    [Required]
    public string Description { get; set; } = string.Empty;

    public bool IsOnSale { get; set; }
}
```

If the [ApiController] attribute is applied, model validation errors result in a 400 status code. For more information, see Automatic HTTP 400 responses.

ActionResult vs IActionResult

The following section compares `ActionResult` to `IActionResult`

ActionResult<T> type

ASP.NET Core includes the ActionResult<T> return type for web API controller actions. It enables returning a type deriving from ActionResult or return a specific type. `ActionResult<T>` offers the following benefits over the IActionResult type:

- The [ProducesResponseType] attribute's `Type` property can be excluded. For example, `[ProducesResponseType(200, Type = typeof(Product))]` is simplified to `[ProducesResponseType(200)]`. The action's expected return type is inferred from the `T` in `ActionResult<T>`.
- Implicit cast operators support the conversion of both `T` and `ActionResult` to `ActionResult<T>`. `T` converts to ObjectResult, which means `return new ObjectResult(T);` is simplified to `return T;`.

C# doesn't support implicit cast operators on interfaces. Consequently, conversion of the interface to a concrete type is necessary to use `ActionResult<T>`. For example, use of `IEnumerable` in the following example doesn't work:

C#

```
[HttpGet]
public ActionResult<IEnumerable<Product>> Get() =>
```

```
    _repository.GetProducts();
```

One option to fix the preceding code is to return `_repository.GetProducts().ToList();`.

Most actions have a specific return type. Unexpected conditions can occur during action execution, in which case the specific type isn't returned. For example, an action's input parameter may fail model validation. In such a case, it's common to return the appropriate `ActionResult` type instead of the specific type.

Synchronous action

Consider a synchronous action in which there are two possible return types:

C#

```
[HttpGet("{id}")]
[ProducesResponseType(StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
public ActionResult<Product> GetById_ActionResultOfT(int id)
{
    var product = _productContext.Products.Find(id);
    return product == null ? NotFound() : product;
}
```

In the preceding action:

- A 404 status code is returned when the product doesn't exist in the database.
- A 200 status code is returned with the corresponding `Product` object when the product does exist.

Asynchronous action

Consider an asynchronous action in which there are two possible return types:

C#

```
[HttpPost()]
[Consumes(MediaTypeNames.Application.Json)]
[ProducesResponseType(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public async Task<ActionResult<Product>> CreateAsync_ActionResultOfT(Product
product)
{
    if (product.Description.Contains("XYZ Widget"))
    {
        return BadRequest();
```

```
    }

    _productContext.Products.Add(product);
    await _productContext.SaveChangesAsync();

    return CreatedAtAction(nameof(CreateAsync_ActionResultOfT), new { id =
product.Id }, product);
}
```

In the preceding action:

- A 400 status code (BadRequest) is returned by the ASP.NET Core runtime when:
  - The [ApiController] attribute has been applied and model validation fails.
  - The product description contains "XYZ Widget".
- A 201 status code is generated by the CreatedAtAction method when a product is created. In this code path, the `Product` object is provided in the response body. A `Location` response header containing the newly created product's URL is provided.

HttpResults type

In addition to the MVC-specific built-in result types (IActionResult and ActionResult<T>), ASP.NET Core includes the HttpResults types that can be used in both Minimal APIs and Web API.

Different than the MVC-specific result types, the `HttpResults`:

- Are a results implementation that is processed by a call to IResult.ExecuteAsync.
- Does ***not*** leverage the configured Formatters. Not leveraging the configured formatters means:
  - Some features like `Content negotiation` aren't available.
  - The produced `Content-Type` is decided by the `HttpResults` implementation.

The `HttpResults` can be useful when sharing code between Minimal APIs and Web API.

IResult type

The Microsoft.AspNetCore.Http.HttpResults namespace contains classes that implement the IResult interface. The `IResult` interface defines a contract that represents the result of an HTTP endpoint. The static Results class is used to create varying `IResult` objects that represent different types of responses.

The Built-in results table shows the common result helpers.

Consider the following code:

```C#
[HttpGet("{id}")]
[ProducesResponseType<Product>(StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
public IResult GetById(int id)
{
    var product = _productContext.Products.Find(id);
    return product == null ? Results.NotFound() : Results.Ok(product);
}
```

In the preceding action:

- A 404 status code is returned when the product doesn't exist in the database.
- A 200 status code is returned with the corresponding `Product` object when the product does exist, generated by the Results.Ok<T>().

Consider the following code:

```C#
[HttpPost]
[Consumes(MediaTypeNames.Application.Json)]
[ProducesResponseType<Product>(StatusCodes.Status201Created)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
public async Task<IResult> CreateAsync(Product product)
{
    if (product.Description.Contains("XYZ Widget"))
    {
        return Results.BadRequest();
    }

    _productContext.Products.Add(product);
    await _productContext.SaveChangesAsync();

    var location = Url.Action(nameof(CreateAsync), new { id = product.Id })
?? $"/{product.Id}";
    return Results.Created(location, product);
}
```

In the preceding action:

- A 400 status code is returned when:
  - The [ApiController] attribute has been applied and model validation fails.
  - The product description contains "XYZ Widget".

- A 201 status code is generated by the Results.Create method when a product is created. In this code path, the `Product` object is provided in the response body. A `Location` response header containing the newly created product's URL is provided.

Results<TResult1, TResultN> type

The static TypedResults class returns the concrete `IResult` implementation that allows using `IResult` as return type. The usage of the concrete `IResult` implementation offers the following benefit over the IResult type:

- All the [ProducesResponseType] attributes can be excluded, since the `HttpResult` implementation contributes automatically to the endpoint metadata.

When multiple `IResult` return types are needed, returning Results<TResult1, TResultN> is preferred over returning `IResult`. Returning `Results<TResult1, TResultN>` is preferred because generic union types automatically retain the endpoint metadata.

The `Results<TResult1, TResultN>` union types implement implicit cast operators so that the compiler can automatically convert the types specified in the generic arguments to an instance of the union type. This has the added benefit of providing compile-time checking that a route handler actually only returns the results that it declares it does. Attempting to return a type that isn't declared as one of the generic arguments to `Results<>` results in a compilation error.

Consider the following code:

C#

```
[HttpGet("{id}")]
public Results<NotFound, Ok<Product>> GetById(int id)
{
    var product = _productContext.Products.Find(id);
    return product == null ? TypedResults.NotFound() :
TypedResults.Ok(product);
}
```

In the preceding action:

- A 404 status code is returned when the product doesn't exist in the database.
- A 200 status code is returned with the corresponding `Product` object when the product does exist, generated by the TypedResults.Ok<T>.

C#

```
[HttpPost]
public async Task<Results<BadRequest, Created<Product>>> CreateAsync(Product
product)
{
    if (product.Description.Contains("XYZ Widget"))
    {
        return TypedResults.BadRequest();
    }

    _productContext.Products.Add(product);
    await _productContext.SaveChangesAsync();

    var location = Url.Action(nameof(CreateAsync), new { id = product.Id })
?? $"/{product.Id}";
    return TypedResults.Created(location, product);
}
```

In the preceding action:

- A 400 status code is returned when:
  - The [ApiController] attribute was applied and model validation fails.
  - The product description contains "XYZ Widget".
- A 201 status code is generated by the TypedResults.Created method when a product is created. In this code path, the `Product` object is provided in the response body. A `Location` response header containing the newly created product's URL is provided.

JsonPatch in ASP.NET Core web API

Article • 03/08/2023

This article explains how to handle JSON Patch requests in an ASP.NET Core web API.

Package installation

JSON Patch support in ASP.NET Core web API is based on `Newtonsoft.Json` and requires the Microsoft.AspNetCore.Mvc.NewtonsoftJson NuGet package. To enable JSON Patch support:

- Install the Microsoft.AspNetCore.Mvc.NewtonsoftJson NuGet package.
- Call AddNewtonsoftJson. For example:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .AddNewtonsoftJson();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

`AddNewtonsoftJson` replaces the default `System.Text.Json`-based input and output formatters used for formatting ***all*** JSON content. This extension method is compatible with the following MVC service registration methods:

- AddRazorPages
- AddControllersWithViews
- AddControllers

JsonPatch requires setting the `Content-Type` header to `application/json-patch+json`.

Add support for JSON Patch when using System.Text.Json

The `System.Text.Json`-based input formatter doesn't support JSON Patch. To add support for JSON Patch using `Newtonsoft.Json`, while leaving the other input and output formatters unchanged:

- Install the Microsoft.AspNetCore.Mvc.NewtonsoftJson NuGet package.
- Update `Program.cs`:

C#

```
using JsonPatchSample;
using Microsoft.AspNetCore.Mvc.Formatters;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    options.InputFormatters.Insert(0,
MyJPIF.GetJsonPatchInputFormatter());
});

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

C#

```
using Microsoft.AspNetCore.Mvc;
using Microsoft.AspNetCore.Mvc.Formatters;
using Microsoft.Extensions.Options;

namespace JsonPatchSample;

public static class MyJPIF
{
    public static NewtonsoftJsonPatchInputFormatter
GetJsonPatchInputFormatter()
    {
        var builder = new ServiceCollection()
            .AddLogging()
```

```
            .AddMvc()
            .AddNewtonsoftJson()
            .Services.BuildServiceProvider();

        return builder
            .GetRequiredService<IOptions<MvcOptions>>()
            .Value
            .InputFormatters
            .OfType<NewtonsoftJsonPatchInputFormatter>()
            .First();
    }
}
```

The preceding code creates an instance of NewtonsoftJsonPatchInputFormatter and inserts it as the first entry in the MvcOptions.InputFormatters collection. This order of registration ensures that:

- `NewtonsoftJsonPatchInputFormatter` processes JSON Patch requests.
- The existing `System.Text.Json`-based input and formatters process all other JSON requests and responses.

Use the `Newtonsoft.Json.JsonConvert.SerializeObject` method to serialize a JsonPatchDocument.

PATCH HTTP request method

The PUT and PATCH methods are used to update an existing resource. The difference between them is that PUT replaces the entire resource, while PATCH specifies only the changes.

JSON Patch

JSON Patch is a format for specifying updates to be applied to a resource. A JSON Patch document has an array of *operations*. Each operation identifies a particular type of change. Examples of such changes include adding an array element or replacing a property value.

For example, the following JSON documents represent a resource, a JSON Patch document for the resource, and the result of applying the Patch operations.

Resource example

```
JSON
```

```
{
  "customerName": "John",
  "orders": [
    {
      "orderName": "Order0",
      "orderType": null
    },
    {
      "orderName": "Order1",
      "orderType": null
    }
  ]
}
```

JSON patch example

JSON

```
[
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "add",
    "path": "/orders/-",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

In the preceding JSON:

- The `op` property indicates the type of operation.
- The `path` property indicates the element to update.
- The `value` property provides the new value.

Resource after patch

Here's the resource after applying the preceding JSON Patch document:

JSON

```
{
  "customerName": "Barry",
  "orders": [
    {
      "orderName": "Order0",
      "orderType": null
    },
    {
      "orderName": "Order1",
      "orderType": null
    },
    {
      "orderName": "Order2",
      "orderType": null
    }
  ]
}
```

The changes made by applying a JSON Patch document to a resource are atomic. If any operation in the list fails, no operation in the list is applied.

Path syntax

The path property of an operation object has slashes between levels. For example, `"/address/zipCode"`.

Zero-based indexes are used to specify array elements. The first element of the `addresses` array would be at `/addresses/0`. To `add` to the end of an array, use a hyphen (`-`) rather than an index number: `/addresses/-`.

Operations

The following table shows supported operations as defined in the JSON Patch specification:

Expand table

Operation	Notes
`add`	Add a property or array element. For existing property: set value.
`remove`	Remove a property or array element.
`replace`	Same as `remove` followed by `add` at same location.

Operation	Notes
`move`	Same as `remove` from source followed by `add` to destination using value from source.
`copy`	Same as `add` to destination using value from source.
`test`	Return success status code if value at `path` = provided `value`.

JSON Patch in ASP.NET Core

The ASP.NET Core implementation of JSON Patch is provided in the Microsoft.AspNetCore.JsonPatch NuGet package.

Action method code

In an API controller, an action method for JSON Patch:

- Is annotated with the `HttpPatch` attribute.
- Accepts a JsonPatchDocument<TModel>, typically with [FromBody].
- Calls ApplyTo(Object) on the patch document to apply the changes.

Here's an example:

C#

```
[HttpPatch]
public IActionResult JsonPatchWithModelState(
    [FromBody] JsonPatchDocument<Customer> patchDoc)
{
    if (patchDoc != null)
    {
        var customer = CreateCustomer();

        patchDoc.ApplyTo(customer, ModelState);

        if (!ModelState.IsValid)
        {
            return BadRequest(ModelState);
        }

        return new ObjectResult(customer);
    }
    else
    {
        return BadRequest(ModelState);
```

```
    }
}
```

This code from the sample app works with the following `Customer` model:

C#

```
namespace JsonPatchSample.Models;

public class Customer
{
    public string? CustomerName { get; set; }
    public List<Order>? Orders { get; set; }
}
```

C#

```
namespace JsonPatchSample.Models;

public class Order
{
    public string OrderName { get; set; }
    public string OrderType { get; set; }
}
```

The sample action method:

- Constructs a `Customer`.
- Applies the patch.
- Returns the result in the body of the response.

In a real app, the code would retrieve the data from a store such as a database and update the database after applying the patch.

Model state

The preceding action method example calls an overload of `ApplyTo` that takes model state as one of its parameters. With this option, you can get error messages in responses. The following example shows the body of a 400 Bad Request response for a `test` operation:

JSON

```
{
  "Customer": [
    "The current value 'John' at path 'customerName' != test value 'Nancy'."
```

```
  ]
}
```

Dynamic objects

The following action method example shows how to apply a patch to a dynamic object:

C#

```
[HttpPatch]
public IActionResult JsonPatchForDynamic([FromBody]JsonPatchDocument patch)
{
    dynamic obj = new ExpandoObject();
    patch.ApplyTo(obj);

    return Ok(obj);
}
```

The add operation

- If `path` points to an array element: inserts new element before the one specified by `path`.
- If `path` points to a property: sets the property value.
- If `path` points to a nonexistent location:
  - If the resource to patch is a dynamic object: adds a property.
  - If the resource to patch is a static object: the request fails.

The following sample patch document sets the value of `CustomerName` and adds an `Order` object to the end of the `Orders` array.

JSON

```
[
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "add",
    "path": "/orders/-",
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
```

```
  }
]
```

The remove operation

- If `path` points to an array element: removes the element.
- If `path` points to a property:
  - If resource to patch is a dynamic object: removes the property.
  - If resource to patch is a static object:
    - If the property is nullable: sets it to null.
    - If the property is non-nullable, sets it to `default<T>`.

The following sample patch document sets `CustomerName` to null and deletes `Orders[0]`:

JSON

```
[
  {
    "op": "remove",
    "path": "/customerName"
  },
  {
    "op": "remove",
    "path": "/orders/0"
  }
]
```

The replace operation

This operation is functionally the same as a `remove` followed by an `add`.

The following sample patch document sets the value of `CustomerName` and replaces `Orders[0]` with a new `Order` object:

JSON

```
[
  {
    "op": "replace",
    "path": "/customerName",
    "value": "Barry"
  },
  {
    "op": "replace",
    "path": "/orders/0",
```

```
    "value": {
      "orderName": "Order2",
      "orderType": null
    }
  }
]
```

The move operation

- If `path` points to an array element: copies `from` element to location of `path` element, then runs a `remove` operation on the `from` element.
- If `path` points to a property: copies value of `from` property to `path` property, then runs a `remove` operation on the `from` property.
- If `path` points to a nonexistent property:
  - If the resource to patch is a static object: the request fails.
  - If the resource to patch is a dynamic object: copies `from` property to location indicated by `path`, then runs a `remove` operation on the `from` property.

The following sample patch document:

- Copies the value of `Orders[0].OrderName` to `CustomerName`.
- Sets `Orders[0].OrderName` to null.
- Moves `Orders[1]` to before `Orders[0]`.

JSON

```
[
  {
    "op": "move",
    "from": "/orders/0/orderName",
    "path": "/customerName"
  },
  {
    "op": "move",
    "from": "/orders/1",
    "path": "/orders/0"
  }
]
```

The copy operation

This operation is functionally the same as a `move` operation without the final `remove` step.

The following sample patch document:

- Copies the value of `Orders[0].OrderName` to `CustomerName`.
- Inserts a copy of `Orders[1]` before `Orders[0]`.

JSON

```
[
  {
    "op": "copy",
    "from": "/orders/0/orderName",
    "path": "/customerName"
  },
  {
    "op": "copy",
    "from": "/orders/1",
    "path": "/orders/0"
  }
]
```

The test operation

If the value at the location indicated by `path` is different from the value provided in `value`, the request fails. In that case, the whole PATCH request fails even if all other operations in the patch document would otherwise succeed.

The `test` operation is commonly used to prevent an update when there's a concurrency conflict.

The following sample patch document has no effect if the initial value of `CustomerName` is "John", because the test fails:

JSON

```
[
  {
    "op": "test",
    "path": "/customerName",
    "value": "Nancy"
  },
  {
    "op": "add",
    "path": "/customerName",
    "value": "Barry"
  }
]
```

Get the code

View or download sample code. (How to download).

To test the sample, run the app and send HTTP requests with the following settings:

- URL: `http://localhost:{port}/jsonpatch/jsonpatchwithmodelstate`
- HTTP method: `PATCH`
- Header: `Content-Type: application/json-patch+json`
- Body: Copy and paste one of the JSON patch document samples from the *JSON* project folder.

Format response data in ASP.NET Core Web API

Article • 07/16/2024

ASP.NET Core MVC supports formatting response data, using specified formats or in response to a client's request.

Format-specific Action Results

Some action result types are specific to a particular format, such as JsonResult and ContentResult. Actions can return results that always use a specified format, ignoring a client's request for a different format. For example, returning `JsonResult` returns JSON-formatted data and returning `ContentResult` returns plain-text-formatted string data.

An action isn't required to return any specific type. ASP.NET Core supports any object return value. Results from actions that return objects that aren't IActionResult types are serialized using the appropriate IOutputFormatter implementation. For more information, see Controller action return types in ASP.NET Core web API.

By default, the built-in helper method ControllerBase.Ok returns JSON-formatted data:

C#

```
[HttpGet]
public IActionResult Get()
    => Ok(_todoItemStore.GetList());
```

The sample code returns a list of todo items. Using the F12 browser developer tools or http-repl with the previous code displays:

- The response header containing **content-type:** `application/json; charset=utf-8`.
- The request headers. For example, the `Accept` header. The `Accept` header is ignored by the preceding code.

To return plain text formatted data, use ContentResult and the Content helper:

C#

```
[HttpGet("Version")]
public ContentResult GetVersion()
    => Content("v1.0.0");
```

In the preceding code, the `Content-Type` returned is `text/plain`.

For actions with multiple return types, return `IActionResult`. For example, when returning different HTTP status codes based on the result of the operation.

Content negotiation

Content negotiation occurs when the client specifies an Accept header. The default format used by ASP.NET Core is JSON. Content negotiation is:

- Implemented by ObjectResult.
- Built into the status code-specific action results returned from the helper methods. The action results helper methods are based on `ObjectResult`.

When a model type is returned, the return type is `ObjectResult`.

The following action method uses the `Ok` and `NotFound` helper methods:

C#

```
[HttpGet("{id:long}")]
public IActionResult GetById(long id)
{
    var todo = _todoItemStore.GetById(id);

    if (todo is null)
    {
        return NotFound();
    }

    return Ok(todo);
}
```

By default, ASP.NET Core supports the following media types:

- `application/json`
- `text/json`
- `text/plain`

Tools such as Fiddler or http-repl can set the `Accept` request header to specify the return format. When the `Accept` header contains a type the server supports, that type is returned. The next section shows how to add additional formatters.

Controller actions can return POCOs (Plain Old CLR Objects). When a POCO is returned, the runtime automatically creates an `ObjectResult` that wraps the object. The client gets

the formatted serialized object. If the object being returned is `null`, a `204 No Content` response is returned.

The following example returns an object type:

```
C#

[HttpGet("{id:long}")]
public TodoItem? GetById(long id)
    => _todoItemStore.GetById(id);
```

In the preceding code, a request for a valid todo item returns a `200 OK` response. A request for an invalid todo item returns a `204 No Content` response.

The Accept header

Content *negotiation* takes place when an `Accept` header appears in the request. When a request contains an accept header, ASP.NET Core:

- Enumerates the media types in the accept header in preference order.
- Tries to find a formatter that can produce a response in one of the formats specified.

If no formatter is found that can satisfy the client's request, ASP.NET Core:

- Returns `406 Not Acceptable` if MvcOptions.ReturnHttpNotAcceptable is set to `true`, or -
- Tries to find the first formatter that can produce a response.

If no formatter is configured for the requested format, the first formatter that can format the object is used. If no `Accept` header appears in the request:

- The first formatter that can handle the object is used to serialize the response.
- There isn't any negotiation taking place. The server is determining what format to return.

If the Accept header contains `*/*`, the Header is ignored unless `RespectBrowserAcceptHeader` is set to true on MvcOptions.

Browsers and content negotiation

Unlike typical API clients, web browsers supply `Accept` headers. Web browsers specify many formats, including wildcards. By default, when the framework detects that the

request is coming from a browser:

- The `Accept` header is ignored.
- The content is returned in JSON, unless otherwise configured.

This approach provides a more consistent experience across browsers when consuming APIs.

To configure an app to respect browser accept headers, set the RespectBrowserAcceptHeader property to `true`:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    options.RespectBrowserAcceptHeader = true;
});
```

Configure formatters

Apps that need to support extra formats can add the appropriate NuGet packages and configure support. There are separate formatters for input and output. Input formatters are used by Model Binding. Output formatters are used to format responses. For information on creating a custom formatter, see Custom Formatters.

Add XML format support

To configure XML formatters implemented using XmlSerializer, call AddXmlSerializerFormatters:

```
C#

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .AddXmlSerializerFormatters();
```

When using the preceding code, controller methods return the appropriate format based on the request's `Accept` header.

Configure `System.Text.Json`-based formatters

To configure features for the `System.Text.Json`-based formatters, use Microsoft.AspNetCore.Mvc.JsonOptions.JsonSerializerOptions. The following highlighted code configures PascalCase formatting instead of the default camelCase formatting:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .AddJsonOptions(options =>
    {
        options.JsonSerializerOptions.PropertyNamingPolicy = null;
    });
```

To configure output serialization options for specific actions, use JsonResult. For example:

C#

```
[HttpGet]
public IActionResult Get()
    => new JsonResult(
        _todoItemStore.GetList(),
        new JsonSerializerOptions { PropertyNamingPolicy = null });
```

Add `Newtonsoft.Json`-based JSON format support

The default JSON formatters use `System.Text.Json`. To use the `Newtonsoft.Json`-based formatters, install the Microsoft.AspNetCore.Mvc.NewtonsoftJson NuGet package and configure it in `Program.cs`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .AddNewtonsoftJson();
```

In the preceding code, the call to `AddNewtonsoftJson` configures the following Web API, MVC, and Razor Pages features to use `Newtonsoft.Json`:

- Input and output formatters that read and write JSON
- JsonResult
- JSON Patch
- IJsonHelper

- TempData

Some features may not work well with `System.Text.Json`-based formatters and require a reference to the `Newtonsoft.Json`-based formatters. Continue using the `Newtonsoft.Json`-based formatters when the app:

- Uses `Newtonsoft.Json` attributes. For example, `[JsonProperty]` or `[JsonIgnore]`.
- Customizes the serialization settings.
- Relies on features that `Newtonsoft.Json` provides.

To configure features for the `Newtonsoft.Json`-based formatters, use SerializerSettings:

C#

```
builder.Services.AddControllers()
    .AddNewtonsoftJson(options =>
    {
        options.SerializerSettings.ContractResolver = new
DefaultContractResolver();
    });
```

To configure output serialization options for specific actions, use `JsonResult`. For example:

C#

```
[HttpGet]
public IActionResult GetNewtonsoftJson()
    => new JsonResult(
        _todoItemStore.GetList(),
        new JsonSerializerSettings { ContractResolver = new
DefaultContractResolver() });
```

Format `ProblemDetails` and `ValidationProblemDetails` responses

The following action method calls ControllerBase.Problem to create a ProblemDetails response:

C#

```
[HttpGet("Error")]
public IActionResult GetError()
    => Problem("Something went wrong.");
```

A `ProblemDetails` response is always camelCase, even when the app sets the format to PascalCase. `ProblemDetails` follows RFC 7807, which specifies lowercase.

When the [ApiController] attribute is applied to a controller class, the controller creates a ValidationProblemDetails response when Model Validation fails. This response includes a dictionary that uses the model's property names as error keys, unchanged. For example, the following model includes a single property that requires validation:

C#

```
public class SampleModel
{
    [Range(1, 10)]
    public int Value { get; set; }
}
```

By default, the `ValidationProblemDetails` response returned when the `Value` property is invalid uses an error key of `Value`, as shown in the following example:

C#

```
{
  "type": "https://tools.ietf.org/html/rfc7231#section-6.5.1",
  "title": "One or more validation errors occurred.",
  "status": 400,
  "traceId": "00-00000000000000000000000000000000-0000000000000000-00",
  "errors": {
    "Value": [
      "The field Value must be between 1 and 10."
    ]
  }
}
```

To format the property names used as error keys, add an implementation of IMetadataDetailsProvider to the MvcOptions.ModelMetadataDetailsProviders collection. The following example adds a `System.Text.Json`-based implementation, `SystemTextJsonValidationMetadataProvider`, which formats property names as camelCase by default:

C#

```
builder.Services.AddControllers();

builder.Services.Configure<MvcOptions>(options =>
{
    options.ModelMetadataDetailsProviders.Add(
```

```
        new SystemTextJsonValidationMetadataProvider());
});
```

`SystemTextJsonValidationMetadataProvider` also accepts an implementation of JsonNamingPolicy in its constructor, which specifies a custom naming policy for formatting property names.

To set a custom name for a property within a model, use the [JsonPropertyName] attribute on the property:

C#

```
public class SampleModel
{
    [Range(1, 10)]
    [JsonPropertyName("sampleValue")]
    public int Value { get; set; }
}
```

The `ValidationProblemDetails` response returned for the preceding model when the `Value` property is invalid uses an error key of `sampleValue`, as shown in the following example:

C#

```
{
  "type": "https://tools.ietf.org/html/rfc7231#section-6.5.1",
  "title": "One or more validation errors occurred.",
  "status": 400,
  "traceId": "00-00000000000000000000000000000000-0000000000000000-00",
  "errors": {
    "sampleValue": [
      "The field Value must be between 1 and 10."
    ]
  }
}
```

To format the `ValidationProblemDetails` response using `Newtonsoft.Json`, use `NewtonsoftJsonValidationMetadataProvider`:

C#

```
builder.Services.AddControllers()
    .AddNewtonsoftJson();

builder.Services.Configure<MvcOptions>(options =>
{
```

```
    options.ModelMetadataDetailsProviders.Add(
        new NewtonsoftJsonValidationMetadataProvider());
});
```

By default, `NewtonsoftJsonValidationMetadataProvider` formats property names as camelCase. `NewtonsoftJsonValidationMetadataProvider` also accepts an implementation of `NamingPolicy` in its constructor, which specifies a custom naming policy for formatting property names. To set a custom name for a property within a model, use the `[JsonProperty]` attribute.

Specify a format

To restrict the response formats, apply the [Produces] filter. Like most Filters, `[Produces]` can be applied at the action, controller, or global scope:

C#

```
[ApiController]
[Route("api/[controller]")]
[Produces("application/json")]
public class TodoItemsController : ControllerBase
```

The preceding [Produces] filter:

- Forces all actions within the controller to return JSON-formatted responses for POCOs (Plain Old CLR Objects) or ObjectResult and its derived types.
- Return JSON-formatted responses even if other formatters are configured and the client specifies a different format.

For more information, see Filters.

Special case formatters

Some special cases are implemented using built-in formatters. By default, `string` return types are formatted as *text/plain* (*text/html* if requested via the `Accept` header). This behavior can be deleted by removing the StringOutputFormatter. Formatters are removed in `Program.cs`. Actions that have a model object return type return `204 No Content` when returning `null`. This behavior can be deleted by removing the HttpNoContentOutputFormatter. The following code removes the `StringOutputFormatter` and `HttpNoContentOutputFormatter`.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    // using Microsoft.AspNetCore.Mvc.Formatters;
    options.OutputFormatters.RemoveType<StringOutputFormatter>();
    options.OutputFormatters.RemoveType<HttpNoContentOutputFormatter>();
});
```

Without the `StringOutputFormatter`, the built-in JSON formatter formats `string` return types. If the built-in JSON formatter is removed and an XML formatter is available, the XML formatter formats `string` return types. Otherwise, `string` return types return `406 Not Acceptable`.

Without the `HttpNoContentOutputFormatter`, null objects are formatted using the configured formatter. For example:

- The JSON formatter returns a response with a body of `null`.
- The XML formatter returns an empty XML element with the attribute `xsi:nil="true"` set.

Response format URL mappings

Clients can request a particular format as part of the URL, for example:

- In the query string or part of the path.
- By using a format-specific file extension such as .xml or .json.

The mapping from request path should be specified in the route the API is using. For example:

C#

```
[ApiController]
[Route("api/[controller]")]
[FormatFilter]
public class TodoItemsController : ControllerBase
{
    private readonly TodoItemStore _todoItemStore;

    public TodoItemsController(TodoItemStore todoItemStore)
        => _todoItemStore = todoItemStore;

    [HttpGet("{id:long}.{format?}")]
```

```
    public TodoItem? GetById(long id)
        => _todoItemStore.GetById(id);
```

The preceding route allows the requested format to be specified using an optional file extension. The [FormatFilter] attribute checks for the existence of the format value in the `RouteData` and maps the response format to the appropriate formatter when the response is created.

Expand table

Route	Formatter
`/api/todoitems/5`	The default output formatter
`/api/todoitems/5.json`	The JSON formatter (if configured)
`/api/todoitems/5.xml`	The XML formatter (if configured)

Polymorphic deserialization

Built-in features provide a limited range of polymorphic serialization but no support for deserialization at all. Deserialization requires a custom converter. See Polymorphic deserialization for a complete sample of polymorphic deserialization.

Custom formatters in ASP.NET Core Web API

Article • 07/16/2024

ASP.NET Core MVC supports data exchange in Web APIs using input and output formatters. Input formatters are used by Model Binding. Output formatters are used to format responses.

The framework provides built-in input and output formatters for JSON and XML. It provides a built-in output formatter for plain text, but doesn't provide an input formatter for plain text.

This article shows how to add support for additional formats by creating custom formatters. For an example of a custom plain text input formatter, see TextPlainInputFormatter on GitHub.

View or download sample code (how to download)

When to use a custom formatter

Use a custom formatter to add support for a content type that isn't handled by the built-in formatters.

Overview of how to create a custom formatter

To create a custom formatter:

- For serializing data sent to the client, create an output formatter class.
- For deserializing data received from the client, create an input formatter class.
- Add instances of formatter classes to the InputFormatters and OutputFormatters collections in MvcOptions.

Create a custom formatter

To create a formatter:

- Derive the class from the appropriate base class. The sample app derives from TextOutputFormatter and TextInputFormatter.
- Specify supported media types and encodings in the constructor.
- Override the CanReadType and CanWriteType methods.

- Override the ReadRequestBodyAsync and WriteResponseBodyAsync methods.

The following code shows the `VcardOutputFormatter` class from the sample:

C#

```
public class VcardOutputFormatter : TextOutputFormatter
{
    public VcardOutputFormatter()
    {
        SupportedMediaTypes.Add(MediaTypeHeaderValue.Parse("text/vcard"));

        SupportedEncodings.Add(Encoding.UTF8);
        SupportedEncodings.Add(Encoding.Unicode);
    }

    protected override bool CanWriteType(Type? type)
        => typeof(Contact).IsAssignableFrom(type)
            || typeof(IEnumerable<Contact>).IsAssignableFrom(type);

    public override async Task WriteResponseBodyAsync(
        OutputFormatterWriteContext context, Encoding selectedEncoding)
    {
        var httpContext = context.HttpContext;
        var serviceProvider = httpContext.RequestServices;

        var logger =
serviceProvider.GetRequiredService<ILogger<VcardOutputFormatter>>();
        var buffer = new StringBuilder();

        if (context.Object is IEnumerable<Contact> contacts)
        {
            foreach (var contact in contacts)
            {
                FormatVcard(buffer, contact, logger);
            }
        }
        else
        {
            FormatVcard(buffer, (Contact)context.Object!, logger);
        }

        await httpContext.Response.WriteAsync(buffer.ToString(),
selectedEncoding);
    }

    private static void FormatVcard(
        StringBuilder buffer, Contact contact, ILogger logger)
    {
        buffer.AppendLine("BEGIN:VCARD");
        buffer.AppendLine("VERSION:2.1");
        buffer.AppendLine($"N:{contact.LastName};{contact.FirstName}");
        buffer.AppendLine($"FN:{contact.FirstName} {contact.LastName}");
        buffer.AppendLine($"UID:{contact.Id}");
```

```
            buffer.AppendLine("END:VCARD");

            logger.LogInformation("Writing {FirstName} {LastName}",
                contact.FirstName, contact.LastName);
        }
    }
```

Derive from the appropriate base class

For text media types (for example, vCard), derive from the TextInputFormatter or TextOutputFormatter base class:

C#

```
public class VcardOutputFormatter : TextOutputFormatter
```

For binary types, derive from the InputFormatter or OutputFormatter base class.

Specify supported media types and encodings

In the constructor, specify supported media types and encodings by adding to the SupportedMediaTypes and SupportedEncodings collections:

C#

```
public VcardOutputFormatter()
{
    SupportedMediaTypes.Add(MediaTypeHeaderValue.Parse("text/vcard"));

    SupportedEncodings.Add(Encoding.UTF8);
    SupportedEncodings.Add(Encoding.Unicode);
}
```

A formatter class can **not** use constructor injection for its dependencies. For example, `ILogger<VcardOutputFormatter>` can't be added as a parameter to the constructor. To access services, use the context object that gets passed in to the methods. A code example in this article and the sample show how to do this.

Override CanReadType and CanWriteType

Specify the type to deserialize into or serialize from by overriding the CanReadType or CanWriteType methods. For example, to create vCard text from a `Contact` type and vice versa:

C#

```
protected override bool CanWriteType(Type? type)
    => typeof(Contact).IsAssignableFrom(type)
        || typeof(IEnumerable<Contact>).IsAssignableFrom(type);
```

The CanWriteResult method

In some scenarios, CanWriteResult must be overridden rather than CanWriteType. Use `CanWriteResult` if the following conditions are true:

- The action method returns a model class.
- There are derived classes that might be returned at runtime.
- The derived class returned by the action must be known at runtime.

For example, suppose the action method:

- Signature returns a `Person` type.
- Can return a `Student` or `Instructor` type that derives from `Person`.

For the formatter to handle only `Student` objects, check the type of Object in the context object provided to the `CanWriteResult` method. When the action method returns IActionResult:

- It's not necessary to use `CanWriteResult`.
- The `CanWriteType` method receives the runtime type.

Override ReadRequestBodyAsync and WriteResponseBodyAsync

Deserialization or serialization is performed in ReadRequestBodyAsync or WriteResponseBodyAsync. The following example shows how to get services from the dependency injection container. Services can't be obtained from constructor parameters:

C#

```
public override async Task WriteResponseBodyAsync(
    OutputFormatterWriteContext context, Encoding selectedEncoding)
{
    var httpContext = context.HttpContext;
    var serviceProvider = httpContext.RequestServices;

    var logger =
```

```
serviceProvider.GetRequiredService<ILogger<VcardOutputFormatter>>();
    var buffer = new StringBuilder();

    if (context.Object is IEnumerable<Contact> contacts)
    {
        foreach (var contact in contacts)
        {
            FormatVcard(buffer, contact, logger);
        }
    }
    else
    {
        FormatVcard(buffer, (Contact)context.Object!, logger);
    }

    await httpContext.Response.WriteAsync(buffer.ToString(),
selectedEncoding);
}

private static void FormatVcard(
    StringBuilder buffer, Contact contact, ILogger logger)
{
    buffer.AppendLine("BEGIN:VCARD");
    buffer.AppendLine("VERSION:2.1");
    buffer.AppendLine($"N:{contact.LastName};{contact.FirstName}");
    buffer.AppendLine($"FN:{contact.FirstName} {contact.LastName}");
    buffer.AppendLine($"UID:{contact.Id}");
    buffer.AppendLine("END:VCARD");

    logger.LogInformation("Writing {FirstName} {LastName}",
        contact.FirstName, contact.LastName);
}
```

Configure MVC to use a custom formatter

To use a custom formatter, add an instance of the formatter class to the MvcOptions.InputFormatters or MvcOptions.OutputFormatters collection:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers(options =>
{
    options.InputFormatters.Insert(0, new VcardInputFormatter());
    options.OutputFormatters.Insert(0, new VcardOutputFormatter());
});
```

Formatters are evaluated in the order they're inserted, where the first one takes precedence.

The complete `VcardInputFormatter` class

The following code shows the `VcardInputFormatter` class from the sample:

C#

```
public class VcardInputFormatter : TextInputFormatter
{
    public VcardInputFormatter()
    {
        SupportedMediaTypes.Add(MediaTypeHeaderValue.Parse("text/vcard"));

        SupportedEncodings.Add(Encoding.UTF8);
        SupportedEncodings.Add(Encoding.Unicode);
    }

    protected override bool CanReadType(Type type)
        => type == typeof(Contact);

    public override async Task<InputFormatterResult> ReadRequestBodyAsync(
        InputFormatterContext context, Encoding effectiveEncoding)
    {
        var httpContext = context.HttpContext;
        var serviceProvider = httpContext.RequestServices;

        var logger =
serviceProvider.GetRequiredService<ILogger<VcardInputFormatter>>();

        using var reader = new StreamReader(httpContext.Request.Body,
effectiveEncoding);
        string? nameLine = null;

        try
        {
            await ReadLineAsync("BEGIN:VCARD", reader, context, logger);
            await ReadLineAsync("VERSION:", reader, context, logger);

            nameLine = await ReadLineAsync("N:", reader, context, logger);

            var split = nameLine.Split(";".ToCharArray());
            var contact = new Contact(FirstName: split[1], LastName:
split[0].Substring(2));

            await ReadLineAsync("FN:", reader, context, logger);
            await ReadLineAsync("END:VCARD", reader, context, logger);

            logger.LogInformation("nameLine = {nameLine}", nameLine);

            return await InputFormatterResult.SuccessAsync(contact);
        }
        catch
        {
            logger.LogError("Read failed: nameLine = {nameLine}", nameLine);
```

```
            return await InputFormatterResult.FailureAsync();
        }
    }

    private static async Task<string> ReadLineAsync(
        string expectedText, StreamReader reader, InputFormatterContext
context,
        ILogger logger)
    {
        var line = await reader.ReadLineAsync();

        if (line is null || !line.StartsWith(expectedText))
        {
            var errorMessage = $"Looked for '{expectedText}' and got
'{line}'";

            context.ModelState.TryAddModelError(context.ModelName,
errorMessage);
            logger.LogError(errorMessage);

            throw new Exception(errorMessage);
        }

        return line;
    }
}
```

Test the app

Run the sample app for this article, which implements basic vCard input and output formatters. The app reads and writes vCards similar to the following format:

```
BEGIN:VCARD
VERSION:2.1
N:Davolio;Nancy
FN:Nancy Davolio
END:VCARD
```

To see vCard output, run the app and send a Get request with Accept header `text/vcard` to `https://localhost:<port>/api/contacts`.

To add a vCard to the in-memory collection of contacts:

- Send a `Post` request to `/api/contacts` with a tool like http-repl.
- Set the `Content-Type` header to `text/vcard`.
- Set `vCard` text in the body, formatted like the preceding example.

Use web API analyzers

Article • 04/10/2024

ASP.NET Core provides an MVC analyzers package intended for use with web API projects. The analyzers work with controllers annotated with ApiControllerAttribute, while building on web API conventions.

The analyzers package notifies you of any controller action that:

- Returns an undeclared status code.
- Returns an undeclared success result.
- Documents a status code that isn't returned.
- Includes an explicit model validation check.

Reference the analyzer package

The analyzers are included in the .NET Core SDK. To enable the analyzer in your project, include the `IncludeOpenAPIAnalyzers` property in the project file:

XML

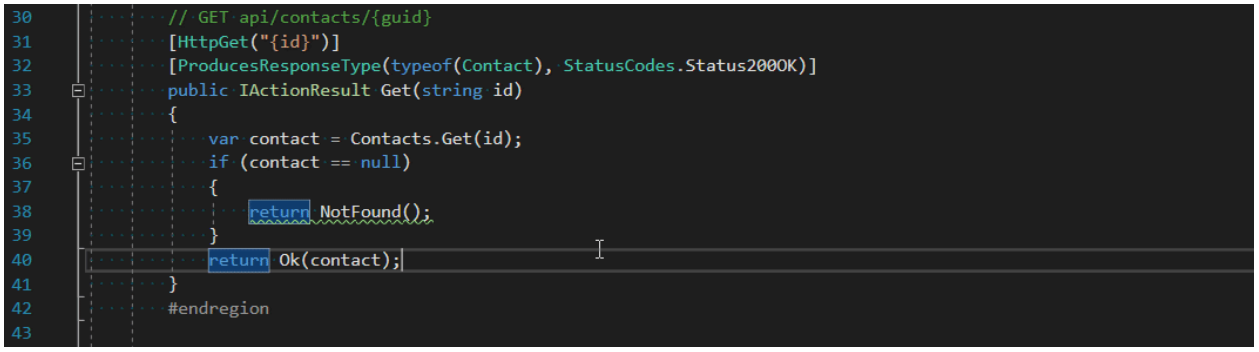
```xml
<PropertyGroup>
 <IncludeOpenAPIAnalyzers>true</IncludeOpenAPIAnalyzers>
</PropertyGroup>
```

Analyzers for web API conventions

OpenAPI documents contain status codes and response types that an action may return. In ASP.NET Core MVC, attributes such as ProducesResponseTypeAttribute and ProducesAttribute are used to document an action. ASP.NET Core web API documentation with Swagger / OpenAPI goes into further detail on documenting your web API.

One of the analyzers in the package inspects controllers annotated with ApiControllerAttribute and identifies actions that don't entirely document their responses. Consider the following example:

C#



```csharp
// GET api/contacts/{guid}
[HttpGet("{id}", Name = "GetById")]
[ProducesResponseType(typeof(Contact), StatusCodes.Status200OK)]
```

```
public IActionResult Get(string id)
{
    var contact = _contacts.Get(id);

    if (contact == null)
    {
        return NotFound();
    }

    return Ok(contact);
}
```

The preceding action documents the HTTP 200 success return type but doesn't document the HTTP 404 failure status code. The analyzer reports the missing documentation for the HTTP 404 status code as a warning. An option to fix the problem is provided.

Analyzers require Microsoft.NET.Sdk.Web

Analyzers don't work with library projects or projects referencing `Sdk="Microsoft.NET.Sdk"`.

Use web API conventions

Article • 04/10/2024

Common API documentation can be extracted and applied to multiple actions, controllers, or all controllers within an assembly. Web API conventions are a substitute for decorating individual actions with [ProducesResponseType].

A convention allows you to:

- Define the most common return types and status codes returned from a specific type of action.
- Identify actions that deviate from the defined standard.

Default conventions are available from Microsoft.AspNetCore.Mvc.DefaultApiConventions. The conventions are demonstrated with the `ValuesController.cs` added to an **API** project template:

C#

```
using Microsoft.AspNetCore.Mvc;
using System.Collections.Generic;

namespace WebApp1.Controllers
{
    [Route("api/[controller]")]
    [ApiController]
    public class ValuesController : ControllerBase
    {
        // GET api/values
        [HttpGet]
        public ActionResult<IEnumerable<string>> Get()
        {
            return new string[] { "value1", "value2" };
        }

        // GET api/values/5
        [HttpGet("{id}")]
        public ActionResult<string> Get(int id)
        {
            return "value";
        }

        // POST api/values
        [HttpPost]
        public void Post([FromBody] string value)
        {
        }

        // PUT api/values/5
```

```
        [HttpPut("{id}")]
        public void Put(int id, [FromBody] string value)
        {
        }

        // DELETE api/values/5
        [HttpDelete("{id}")]
        public void Delete(int id)
        {
        }
    }
}
```

Actions that follow the patterns in the `ValuesController.cs` work with the default conventions. If the default conventions don't meet your needs, see Create web API conventions.

At runtime, Microsoft.AspNetCore.Mvc.ApiExplorer understands conventions. `ApiExplorer` is MVC's abstraction to communicate with OpenAPI (also known as Swagger) document generators. Attributes from the applied convention are associated with an action and are included in the action's OpenAPI documentation. API analyzers also understand conventions. If your action is unconventional (for example, it returns a status code that isn't documented by the applied convention), a warning encourages you to document the status code.

View or download sample code (how to download)

Apply web API conventions

Conventions don't compose; each action may be associated with exactly one convention. More specific conventions take precedence over less specific conventions. The selection is non-deterministic when two or more conventions of the same priority apply to an action. The following options exist to apply a convention to an action, from the most specific to the least specific:

1. `Microsoft.AspNetCore.Mvc.ApiConventionMethodAttribute` — Applies to individual actions and specifies the convention type and the convention method that applies.

   In the following example, the default convention type's `Microsoft.AspNetCore.Mvc.DefaultApiConventions.Put` convention method is applied to the `Update` action:

   ```
   C#
   ```

```
// PUT api/contactsconvention/{guid}
[HttpPut("{id}")]
[ApiConventionMethod(typeof(DefaultApiConventions),
                     nameof(DefaultApiConventions.Put))]
public IActionResult Update(string id, Contact contact)
{
    var contactToUpdate = _contacts.Get(id);

    if (contactToUpdate == null)
    {
        return NotFound();
    }

    _contacts.Update(contact);

    return NoContent();
}
```

The `Microsoft.AspNetCore.Mvc.DefaultApiConventions.Put` convention method applies the following attributes to the action:

C#

```
[ProducesDefaultResponseType]
[ProducesResponseType(StatusCodes.Status204NoContent)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
[ProducesResponseType(StatusCodes.Status400BadRequest)]
```

For more information on `[ProducesDefaultResponseType]`, see Default Response.

2. `Microsoft.AspNetCore.Mvc.ApiConventionTypeAttribute` applied to a controller — Applies the specified convention type to all actions on the controller. A convention method is marked with hints that determine the actions to which the convention method applies. For more information on hints, see Create web API conventions).

   In the following example, the default set of conventions is applied to all actions in *ContactsConventionController*:

   C#

   ```
   [ApiController]
   [ApiConventionType(typeof(DefaultApiConventions))]
   [Route("api/[controller]")]
   public class ContactsConventionController : ControllerBase
   {
   ```

3. `Microsoft.AspNetCore.Mvc.ApiConventionTypeAttribute` applied to an assembly — Applies the specified convention type to all controllers in the current assembly. As a recommendation, apply assembly-level attributes in the `Startup.cs` file.

   In the following example, the default set of conventions is applied to all controllers in the assembly:

   ```
   C#

   [assembly: ApiConventionType(typeof(DefaultApiConventions))]
   namespace ApiConventions
   {
       public class Startup
       {
   ```

Create web API conventions

If the default API conventions don't meet your needs, create your own conventions. A convention is:

- A static type with methods.
- Capable of defining response types and naming requirements on actions.

Response types

These methods are annotated with `[ProducesResponseType]` or `[ProducesDefaultResponseType]` attributes. For example:

```
C#

public static class MyAppConventions
{
    [ProducesResponseType(StatusCodes.Status200OK)]
    [ProducesResponseType(StatusCodes.Status404NotFound)]
    public static void Find(int id)
    {
    }
}
```

If more specific metadata attributes are absent, applying this convention to an assembly enforces that:

- The convention method applies to any action named `Find`.
- A parameter named `id` is present on the `Find` action.

Naming requirements

The `[ApiConventionNameMatch]` and `[ApiConventionTypeMatch]` attributes can be applied to the convention method that determines the actions to which they apply. For example:

C#

```
[ProducesResponseType(StatusCodes.Status200OK)]
[ProducesResponseType(StatusCodes.Status404NotFound)]
[ApiConventionNameMatch(ApiConventionNameMatchBehavior.Prefix)]
public static void Find(
    [ApiConventionNameMatch(ApiConventionNameMatchBehavior.Suffix)]
    int id)
{ }
```

In the preceding example:

- The `Microsoft.AspNetCore.Mvc.ApiExplorer.ApiConventionNameMatchBehavior.Prefix` option applied to the method indicates that the convention matches any action prefixed with "Find". Examples of matching actions include `Find`, `FindPet`, and `FindById`.
- The `Microsoft.AspNetCore.Mvc.ApiExplorer.ApiConventionNameMatchBehavior.Suffix` applied to the parameter indicates that the convention matches methods with exactly one parameter ending in the suffix identifier. Examples include parameters such as `id` or `petId`. `ApiConventionTypeMatch` can be similarly applied to types to constrain the parameter type. A `params[]` argument indicates remaining parameters that don't need to be explicitly matched.

Handle errors in ASP.NET Core controller-based web APIs

Article • 08/02/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This article describes how to handle errors and customize error handling in controller-based ASP.NET Core web APIs. For information about error handling in minimal APIs, see Handle errors in ASP.NET Core and Handle errors in minimal APIs.

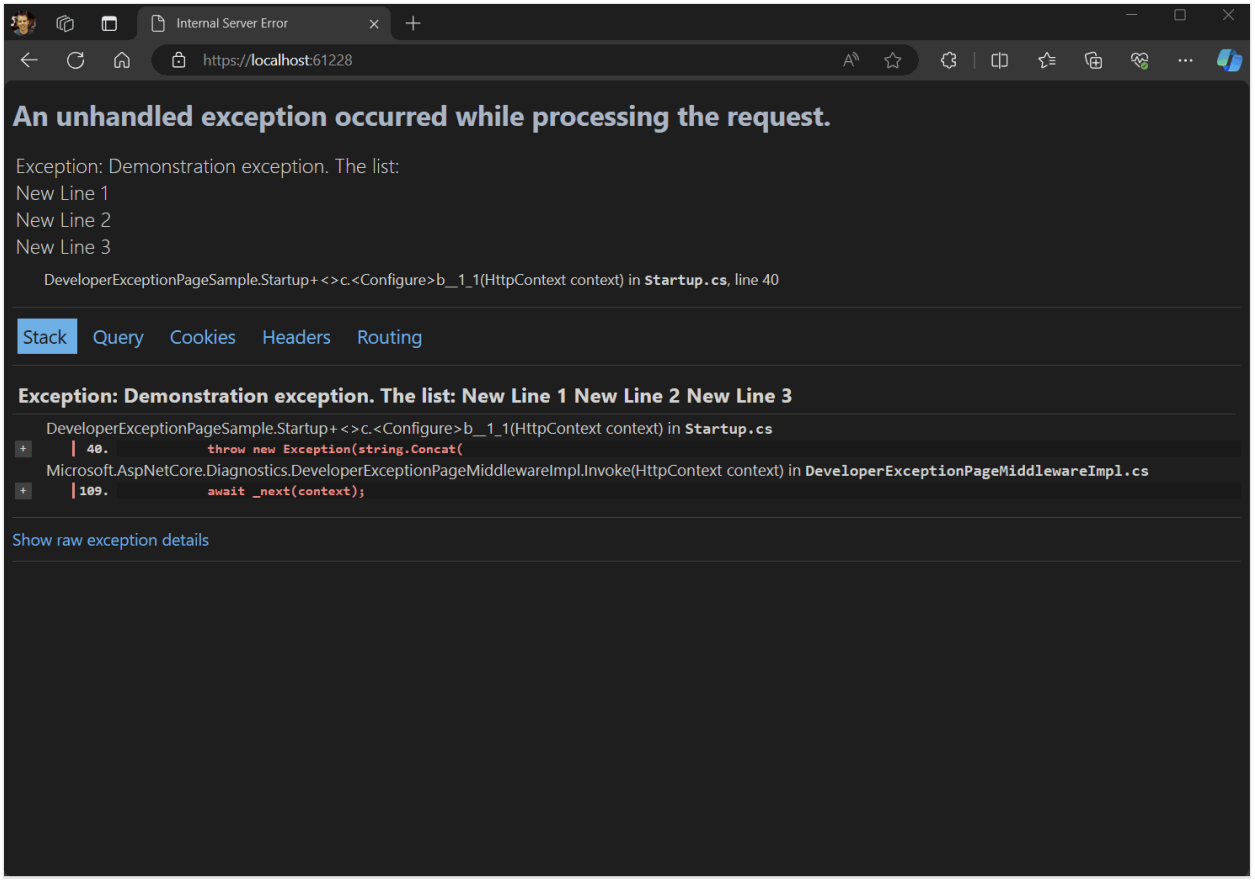
Developer Exception Page

The *Developer Exception Page* displays detailed information about unhandled request exceptions. It uses DeveloperExceptionPageMiddleware to capture synchronous and asynchronous exceptions from the HTTP pipeline and to generate error responses. The developer exception page runs early in the middleware pipeline, so that it can catch unhandled exceptions thrown in middleware that follows.

ASP.NET Core apps enable the developer exception page by default when both:

- Running in the Development environment.
- The app was created with the current templates, that is, by using WebApplication.CreateBuilder.

Apps created using earlier templates, that is, by using WebHost.CreateDefaultBuilder, can enable the developer exception page by calling app.UseDeveloperExceptionPage.



> **⚠ Warning**
>
> Don't enable the Developer Exception Page **unless the app is running in the Development environment**. Don't share detailed exception information publicly when the app runs in production. For more information on configuring environments, see **Use multiple environments in ASP.NET Core**.

The Developer Exception Page can include the following information about the exception and the request:

- Stack trace
- Query string parameters, if any
- Cookies, if any
- Headers
- Endpoint metadata, if any

The Developer Exception Page isn't guaranteed to provide any information. Use Logging for complete error information.

The following image shows a sample developer exception page with animation to show the tabs and the information displayed:

In response to a request with an `Accept: text/plain` header, the Developer Exception Page returns plain text instead of HTML. For example:

text

```
Status: 500 Internal Server Error
Time: 9.39 msSize: 480 bytes
FormattedRawHeadersRequest
Body
text/plain; charset=utf-8, 480 bytes
System.InvalidOperationException: Sample Exception
```

```
   at WebApplicationMinimal.Program.<>c.<Main>b__0_0() in
C:\Source\WebApplicationMinimal\Program.cs:line 12
   at lambda_method1(Closure, Object, HttpContext)
   at
Microsoft.AspNetCore.Diagnostics.DeveloperExceptionPageMiddlewareImpl.Invoke
(HttpContext context)

HEADERS
=======
Accept: text/plain
Host: localhost:7267
traceparent: 00-0eab195ea19d07b90a46cd7d6bf2f
```

To see the Developer Exception Page:

- Add the following controller action to a controller-based API. The action throws an exception when the endpoint is requested.

  C#

  ```
  [HttpGet("Throw")]
  public IActionResult Throw() =>
      throw new Exception("Sample exception.");
  ```

- Run the app in the development environment.
- Go to the endpoint defined by the controller action.

Exception handler

In non-development environments, use Exception Handling Middleware to produce an error payload:

1. In `Program.cs`, call UseExceptionHandler to add the Exception Handling Middleware:

   C#

   ```
   var app = builder.Build();

   app.UseHttpsRedirection();

   if (!app.Environment.IsDevelopment())
   {
       app.UseExceptionHandler("/error");
   }

   app.UseAuthorization();
   ```

```
app.MapControllers();

app.Run();
```

2. Configure a controller action to respond to the `/error` route:

```
C#

[Route("/error")]
public IActionResult HandleError() =>
    Problem();
```

The preceding `HandleError` action sends an RFC 7807 -compliant payload to the client.

> **⚠ Warning**
>
> Don't mark the error handler action method with HTTP method attributes, such as `HttpGet`. Explicit verbs prevent some requests from reaching the action method.
>
> For web APIs that use Swagger / OpenAPI, mark the error handler action with the [ApiExplorerSettings] attribute and set its IgnoreApi property to `true`. This attribute configuration excludes the error handler action from the app's OpenAPI specification:
>
> ```
> C#
>
> [ApiExplorerSettings(IgnoreApi = true)]
> ```
>
> Allow anonymous access to the method if unauthenticated users should see the error.

Exception Handling Middleware can also be used in the Development environment to produce a consistent payload format across all environments:

1. In `Program.cs`, register environment-specific Exception Handling Middleware instances:

```
C#

if (app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/error-development");
}
```

```
else
{
    app.UseExceptionHandler("/error");
}
```

In the preceding code, the middleware is registered with:

- A route of `/error-development` in the Development environment.
- A route of `/error` in non-Development environments.

2. Add controller actions for both the Development and non-Development routes:

```
C#

[Route("/error-development")]
public IActionResult HandleErrorDevelopment(
    [FromServices] IHostEnvironment hostEnvironment)
{
    if (!hostEnvironment.IsDevelopment())
    {
        return NotFound();
    }

    var exceptionHandlerFeature =
        HttpContext.Features.Get<IExceptionHandlerFeature>()!;

    return Problem(
        detail: exceptionHandlerFeature.Error.StackTrace,
        title: exceptionHandlerFeature.Error.Message);
}

[Route("/error")]
public IActionResult HandleError() =>
    Problem();
```

Use exceptions to modify the response

The contents of the response can be modified from outside of the controller using a custom exception and an action filter:

1. Create a well-known exception type named `HttpResponseException`:

```
C#

public class HttpResponseException : Exception
{
    public HttpResponseException(int statusCode, object? value = null)
=>
```

```
        (StatusCode, Value) = (statusCode, value);

    public int StatusCode { get; }

    public object? Value { get; }
}
```

2. Create an action filter named `HttpResponseExceptionFilter`:

```C#
public class HttpResponseExceptionFilter : IActionFilter,
IOrderedFilter
{
    public int Order => int.MaxValue - 10;

    public void OnActionExecuting(ActionExecutingContext context) { }

    public void OnActionExecuted(ActionExecutedContext context)
    {
        if (context.Exception is HttpResponseException
httpResponseException)
        {
            context.Result = new
ObjectResult(httpResponseException.Value)
            {
                StatusCode = httpResponseException.StatusCode
            };

            context.ExceptionHandled = true;
        }
    }
}
```

   The preceding filter specifies an `Order` of the maximum integer value minus 10. This `Order` allows other filters to run at the end of the pipeline.

3. In `Program.cs`, add the action filter to the filters collection:

```C#
builder.Services.AddControllers(options =>
{
    options.Filters.Add<HttpResponseExceptionFilter>();
});
```

Validation failure error response

For web API controllers, MVC responds with a ValidationProblemDetails response type when model validation fails. MVC uses the results of InvalidModelStateResponseFactory to construct the error response for a validation failure. The following example replaces the default factory with an implementation that also supports formatting responses as XML, in `Program.cs`:

C#

```
builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.InvalidModelStateResponseFactory = context =>
            new BadRequestObjectResult(context.ModelState)
            {
                ContentTypes =
                {
                    // using static System.Net.Mime.MediaTypeNames;
                    Application.Json,
                    Application.Xml
                }
            };
    })
    .AddXmlSerializerFormatters();
```

Client error response

An *error result* is defined as a result with an HTTP status code of 400 or higher. For web API controllers, MVC transforms an error result to produce a ProblemDetails.

The automatic creation of a `ProblemDetails` for error status codes is enabled by default, but error responses can be configured in one of the following ways:

1. Use the problem details service
2. Implement ProblemDetailsFactory
3. Use ApiBehaviorOptions.ClientErrorMapping

Default problem details response

The following `Program.cs` file was generated by the web application templates for API controllers:

C#

```
var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddControllers();

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

Consider the following controller, which returns BadRequest when the input is invalid:

C#

```
[Route("api/[controller]/[action]")]
[ApiController]
public class Values2Controller : ControllerBase
{
    // /api/values2/divide/1/2
    [HttpGet("{Numerator}/{Denominator}")]
    public IActionResult Divide(double Numerator, double Denominator)
    {
        if (Denominator == 0)
        {
            return BadRequest();
        }

        return Ok(Numerator / Denominator);
    }

    // /api/values2 /squareroot/4
    [HttpGet("{radicand}")]
    public IActionResult Squareroot(double radicand)
    {
        if (radicand < 0)
        {
            return BadRequest();
        }

        return Ok(Math.Sqrt(radicand));
    }
}
```

A problem details response is generated with the preceding code when any of the following conditions apply:

- The `/api/values2/divide` endpoint is called with a zero denominator.
- The `/api/values2/squareroot` endpoint is called with a radicand less than zero.

The default problem details response body has the following `type`, `title`, and `status` values:

JSON

```
{
  "type": "https://tools.ietf.org/html/rfc7231#section-6.5.1",
  "title": "Bad Request",
  "status": 400,
  "traceId": "00-84c1fd4063c38d9f3900d06e56542d48-85d1d4-00"
}
```

Problem details service

ASP.NET Core supports creating Problem Details for HTTP APIs using the IProblemDetailsService. For more information, see the Problem details service.

The following code configures the app to generate a problem details response for all HTTP client and server error responses that ***don't have body content yet***:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseExceptionHandler();
app.UseStatusCodePages();

if (app.Environment.IsDevelopment())
{
    app.UseDeveloperExceptionPage();
}

app.MapControllers();
app.Run();
```

Consider the API controller from the preceding section, which returns BadRequest when the input is invalid:

C#

```
[Route("api/[controller]/[action]")]
[ApiController]
public class Values2Controller : ControllerBase
```

```
{
    // /api/values2/divide/1/2
    [HttpGet("{Numerator}/{Denominator}")]
    public IActionResult Divide(double Numerator, double Denominator)
    {
        if (Denominator == 0)
        {
            return BadRequest();
        }

        return Ok(Numerator / Denominator);
    }

    // /api/values2 /squareroot/4
    [HttpGet("{radicand}")]
    public IActionResult Squareroot(double radicand)
    {
        if (radicand < 0)
        {
            return BadRequest();
        }

        return Ok(Math.Sqrt(radicand));
    }
}
```

A problem details response is generated with the preceding code when any of the following conditions apply:

- An invalid input is supplied.
- The URI has no matching endpoint.
- An unhandled exception occurs.

The automatic creation of a `ProblemDetails` for error status codes is disabled when the SuppressMapClientErrors property is set to `true`:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.SuppressMapClientErrors = true;
    });

var app = builder.Build();

app.UseHttpsRedirection();

app.UseAuthorization();
```

```
app.MapControllers();

app.Run();
```

Using the preceding code, when an API controller returns `BadRequest`, an HTTP 400 response status is returned with no response body. `SuppressMapClientErrors` prevents a `ProblemDetails` response from being created, even when calling `WriteAsync` for an API Controller endpoint. `WriteAsync` is explained later in this article.

The next section shows how to customize the problem details response body, using CustomizeProblemDetails, to return a more helpful response. For more customization options, see Customizing problem details.

Customize problem details with `CustomizeProblemDetails`

The following code uses ProblemDetailsOptions to set CustomizeProblemDetails:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();

builder.Services.AddProblemDetails(options =>
        options.CustomizeProblemDetails = (context) =>
        {

            var mathErrorFeature = context.HttpContext.Features

.Get<MathErrorFeature>();
            if (mathErrorFeature is not null)
            {
                (string Detail, string Type) details =
mathErrorFeature.MathError switch
                {
                    MathErrorType.DivisionByZeroError =>
                    ("Divison by zero is not defined.",

"https://wikipedia.org/wiki/Division_by_zero"),
                    _ => ("Negative or complex numbers are not valid
input.",

"https://wikipedia.org/wiki/Square_root")
                };

                context.ProblemDetails.Type = details.Type;
                context.ProblemDetails.Title = "Bad Input";
                context.ProblemDetails.Detail = details.Detail;
```

```
            }
        }
    );

var app = builder.Build();

app.UseHttpsRedirection();

app.UseStatusCodePages();

app.UseAuthorization();

app.MapControllers();

app.Run();
```

The updated API controller:

C#

```
[Route("api/[controller]/[action]")]
[ApiController]
public class ValuesController : ControllerBase
{
    // /api/values/divide/1/2
    [HttpGet("{Numerator}/{Denominator}")]
    public IActionResult Divide(double Numerator, double Denominator)
    {
        if (Denominator == 0)
        {
            var errorType = new MathErrorFeature
            {
                MathError = MathErrorType.DivisionByZeroError
            };
            HttpContext.Features.Set(errorType);
            return BadRequest();
        }

        return Ok(Numerator / Denominator);
    }

    // /api/values/squareroot/4
    [HttpGet("{radicand}")]
    public IActionResult Squareroot(double radicand)
    {
        if (radicand < 0)
```

```
        {
            var errorType = new MathErrorFeature
            {
                MathError = MathErrorType.NegativeRadicandError
            };
            HttpContext.Features.Set(errorType);
            return BadRequest();
        }
        return Ok(Math.Sqrt(radicand));
    }

}
```

The following code contains the `MathErrorFeature` and `MathErrorType`, which are used with the preceding sample:

C#

```
// Custom Http Request Feature
class MathErrorFeature
{
    public MathErrorType MathError { get; set; }
}

// Custom math errors
enum MathErrorType
{
    DivisionByZeroError,
    NegativeRadicandError
}
```

A problem details response is generated with the preceding code when any of the following conditions apply:

- The `/divide` endpoint is called with a zero denominator.
- The `/squareroot` endpoint is called with a radicand less than zero.
- The URI has no matching endpoint.

The problem details response body contains the following when either `squareroot` endpoint is called with a radicand less than zero:

JSON

```
{
  "type": "https://en.wikipedia.org/wiki/Square_root",
  "title": "Bad Input",
  "status": 400,
```

```
  "detail": "Negative or complex numbers are not allowed."
}
```

View or download sample code

Implement `ProblemDetailsFactory`

MVC uses Microsoft.AspNetCore.Mvc.Infrastructure.ProblemDetailsFactory to produce all instances of ProblemDetails and ValidationProblemDetails. This factory is used for:

- Client error responses
- Validation failure error responses
- ControllerBase.Problem and ControllerBase.ValidationProblem

To customize the problem details response, register a custom implementation of ProblemDetailsFactory in `Program.cs`:

C#

```
builder.Services.AddControllers();
builder.Services.AddTransient<ProblemDetailsFactory,
SampleProblemDetailsFactory>();
```

Use `ApiBehaviorOptions.ClientErrorMapping`

Use the ClientErrorMapping property to configure the contents of the `ProblemDetails` response. For example, the following code in `Program.cs` updates the Link property for 404 responses:

C#

```
builder.Services.AddControllers()
    .ConfigureApiBehaviorOptions(options =>
    {
        options.ClientErrorMapping[StatusCodes.Status404NotFound].Link =
            "https://httpstatuses.com/404";
    });
```

Test web APIs with the HttpRepl

Article • 07/28/2023

The HTTP Read-Eval-Print Loop (REPL) is:

- A lightweight, cross-platform command-line tool that's supported everywhere .NET Core is supported.
- Used for making HTTP requests to test ASP.NET Core web APIs (and non-ASP.NET Core web APIs) and view their results.
- Capable of testing web APIs hosted in any environment, including localhost and Azure App Service.

The following HTTP verbs are supported:

- DELETE
- GET
- HEAD
- OPTIONS
- PATCH
- POST
- PUT

To follow along, view or download the sample ASP.NET Core web API (how to download).

Prerequisites

- .NET Core 3.1 SDK

Installation

To install the HttpRepl, run the following command:

.NET CLI

```
dotnet tool install -g Microsoft.dotnet-httprepl
```

A .NET Core Global Tool is installed from the Microsoft.dotnet-httprepl NuGet package.

> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see **dotnet tool install, --arch option**. For more information, see GitHub issue **dotnet/AspNetCore.Docs #29262**.

On macOS, update the path:

```Bash
export PATH="$HOME/.dotnet/tools:$PATH"
```

Usage

After successful installation of the tool, run the following command to start the HttpRepl:

```Console
httprepl
```

To view the available HttpRepl commands, run one of the following commands:

```Console
httprepl -h
```

```Console
httprepl --help
```

The following output is displayed:

```Console
Usage:
  httprepl [<BASE_ADDRESS>] [options]

Arguments:
  <BASE_ADDRESS> - The initial base address for the REPL.

Options:
```

```
  -h|--help - Show help information.

Once the REPL starts, these commands are valid:

Setup Commands:
Use these commands to configure the tool for your API server

connect        Configures the directory structure and base address of the
api server
set header     Sets or clears a header for all requests. e.g. `set header
content-type application/json`

HTTP Commands:
Use these commands to execute requests against your application.

GET            get - Issues a GET request
POST           post - Issues a POST request
PUT            put - Issues a PUT request
DELETE         delete - Issues a DELETE request
PATCH          patch - Issues a PATCH request
HEAD           head - Issues a HEAD request
OPTIONS        options - Issues a OPTIONS request

Navigation Commands:
The REPL allows you to navigate your URL space and focus on specific APIs
that you are working on.

ls             Show all endpoints for the current path
cd             Append the given directory to the currently selected path, or
move up a path when using `cd ..`

Shell Commands:
Use these commands to interact with the REPL shell.

clear          Removes all text from the shell
echo [on/off]  Turns request echoing on or off, show the request that was
made when using request commands
exit           Exit the shell

REPL Customization Commands:
Use these commands to customize the REPL behavior.

pref [get/set] Allows viewing or changing preferences, e.g. 'pref set
editor.command.default 'C:\\Program Files\\Microsoft VS Code\\Code.exe'`
run            Runs the script at the given path. A script is a set of
commands that can be typed with one command per line
ui             Displays the Swagger UI page, if available, in the default
browser

Use `help <COMMAND>` for more detail on an individual command. e.g. `help
get`.
For detailed tool info, see https://aka.ms/http-repl-doc.
```

The HttpRepl offers command completion. Pressing the `Tab` key iterates through the list of commands that complete the characters or API endpoint that you typed. The following sections outline the available CLI commands.

Connect to the web API

Connect to a web API by running the following command:

```
Console

httprepl <ROOT URI>
```

`<ROOT URI>` is the base URI for the web API. For example:

```
Console

httprepl https://localhost:5001
```

Alternatively, run the following command at any time while the HttpRepl is running:

```
Console

connect <ROOT URI>
```

For example:

```
Console

(Disconnected)> connect https://localhost:5001
```

Manually point to the OpenAPI description for the web API

The connect command above will attempt to find the OpenAPI description automatically. If for some reason it's unable to do so, you can specify the URI of the OpenAPI description for the web API by using the `--openapi` option:

```
Console

connect <ROOT URI> --openapi <OPENAPI DESCRIPTION ADDRESS>
```

For example:

```
Console

(Disconnected)> connect https://localhost:5001 --openapi
/swagger/v1/swagger.json
```

Enable verbose output for details on OpenAPI description searching, parsing, and validation

Specifying the `--verbose` option with the `connect` command will produce more details when the tool searches for the OpenAPI description, parses, and validates it.

```
Console

connect <ROOT URI> --verbose
```

For example:

```
Console

(Disconnected)> connect https://localhost:5001 --verbose
Checking https://localhost:5001/swagger.json... 404 NotFound
Checking https://localhost:5001/swagger/v1/swagger.json... 404 NotFound
Checking https://localhost:5001/openapi.json... Found
Parsing... Successful (with warnings)
The field 'info' in 'document' object is REQUIRED [#/info]
The field 'paths' in 'document' object is REQUIRED [#/paths]
```

Navigate the web API

View available endpoints

To list the different endpoints (controllers) at the current path of the web API address, run the `ls` or `dir` command:

```
Console

https://localhost:5001/> ls
```

The following output format is displayed:

Console

```
.        []
Fruits   [get|post]
People   [get|post]

https://localhost:5001/>
```

The preceding output indicates that there are two controllers available: `Fruits` and `People`. Both controllers support parameterless HTTP GET and POST operations.

Navigating into a specific controller reveals more detail. For example, the following command's output shows the `Fruits` controller also supports HTTP GET, PUT, and DELETE operations. Each of these operations expects an `id` parameter in the route:

Console

```
https://localhost:5001/fruits> ls
.      [get|post]
..     []
{id}   [get|put|delete]

https://localhost:5001/fruits>
```

Alternatively, run the `ui` command to open the web API's Swagger UI page in a browser. For example:

Console

```
https://localhost:5001/> ui
```

Navigate to an endpoint

To navigate to a different endpoint on the web API, run the `cd` command:

Console

```
https://localhost:5001/> cd people
```

The path following the `cd` command is case insensitive. The following output format is displayed:

Console

```
/people    [get|post]

https://localhost:5001/people>
```

Customize the HttpRepl

The HttpRepl's default colors can be customized. Additionally, a default text editor can be defined. The HttpRepl preferences are persisted across the current session and are honored in future sessions. Once modified, the preferences are stored in the following file:

Windows

%USERPROFILE%\.httpreplprefs

The *.httpreplprefs* file is loaded on startup and not monitored for changes at runtime. Manual modifications to the file take effect only after restarting the tool.

View the settings

To view the available settings, run the `pref get` command. For example:

Console

```
https://localhost:5001/> pref get
```

The preceding command displays the available key-value pairs:

Console

```
colors.json=Green
colors.json.arrayBrace=BoldCyan
colors.json.comma=BoldYellow
colors.json.name=BoldMagenta
colors.json.nameSeparator=BoldWhite
colors.json.objectBrace=Cyan
colors.protocol=BoldGreen
colors.status=BoldYellow
```

Set color preferences

Response colorization is currently supported for JSON only. To customize the default HttpRepl tool coloring, locate the key corresponding to the color to be changed. For instructions on how to find the keys, see the View the settings section. For example, change the `colors.json` key value from `Green` to `White` as follows:

Console

```
https://localhost:5001/people> pref set colors.json White
```

Only the allowed colors may be used. Subsequent HTTP requests display output with the new coloring.

When specific color keys aren't set, more generic keys are considered. To demonstrate this fallback behavior, consider the following example:

- If `colors.json.name` doesn't have a value, `colors.json.string` is used.
- If `colors.json.string` doesn't have a value, `colors.json.literal` is used.
- If `colors.json.literal` doesn't have a value, `colors.json` is used.
- If `colors.json` doesn't have a value, the command shell's default text color (`AllowedColors.None`) is used.

Set indentation size

Response indentation size customization is currently supported for JSON only. The default size is two spaces. For example:

JSON

```
[
  {
    "id": 1,
    "name": "Apple"
  },
  {
    "id": 2,
    "name": "Orange"
  },
  {
    "id": 3,
    "name": "Strawberry"
  }
]
```

To change the default size, set the `formatting.json.indentSize` key. For example, to always use four spaces:

Console

```
pref set formatting.json.indentSize 4
```

Subsequent responses honor the setting of four spaces:

JSON

```
[
    {
        "id": 1,
        "name": "Apple"
    },
    {
        "id": 2,
        "name": "Orange"
    },
    {
        "id": 3,
        "name": "Strawberry"
    }
]
```

Set the default text editor

By default, the HttpRepl has no text editor configured for use. To test web API methods requiring an HTTP request body, a default text editor must be set. The HttpRepl tool launches the configured text editor for the sole purpose of composing the request body. Run the following command to set your preferred text editor as the default:

Console

```
pref set editor.command.default "<EXECUTABLE>"
```

In the preceding command, `<EXECUTABLE>` is the full path to the text editor's executable file. For example, run the following command to set Visual Studio Code as the default text editor:

Windows

Console

```
pref set editor.command.default "C:\Program Files\Microsoft VS
Code\Code.exe"
```

To launch the default text editor with specific CLI arguments, set the `editor.command.default.arguments` key. For example, assume Visual Studio Code is the default text editor and that you always want the HttpRepl to open Visual Studio Code in a new session with extensions disabled. Run the following command:

Console

```
pref set editor.command.default.arguments "--disable-extensions --new-
window"
```

> **Tip**
>
> If your default editor is Visual Studio Code, you'll usually want to pass the `-w` or `--wait` argument to force Visual Studio Code to wait for you to close the file before returning.

Set the OpenAPI Description search paths

By default, the HttpRepl has a set of relative paths that it uses to find the OpenAPI description when executing the `connect` command without the `--openapi` option. These relative paths are combined with the root and base paths specified in the `connect` command. The default relative paths are:

- `swagger.json`
- `swagger/v1/swagger.json`
- `/swagger.json`
- `/swagger/v1/swagger.json`
- `openapi.json`
- `/openapi.json`

To use a different set of search paths in your environment, set the `swagger.searchPaths` preference. The value must be a pipe-delimited list of relative paths. For example:

Console

```
pref set swagger.searchPaths
"swagger/v2/swagger.json|swagger/v3/swagger.json"
```

Instead of replacing the default list altogether, the list can also be modified by adding or removing paths.

To add one or more search paths to the default list, set the `swagger.addToSearchPaths` preference. The value must be a pipe-delimited list of relative paths. For example:

```
Console

pref set swagger.addToSearchPaths
"openapi/v2/openapi.json|openapi/v3/openapi.json"
```

To remove one or more search paths from the default list, set the `swagger.addToSearchPaths` preference. The value must be a pipe-delimited list of relative paths. For example:

```
Console

pref set swagger.removeFromSearchPaths "swagger.json|/swagger.json"
```

Test HTTP GET requests

Synopsis

```
Console

get <PARAMETER> [-F|--no-formatting] [-h|--header] [--response:body] [--
response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

The following options are available for the `get` command:

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Example

To issue an HTTP GET request:

1. Run the `get` command on an endpoint that supports it:

   Console

   ```
   https://localhost:5001/people> get
   ```

   The preceding command displays the following output format:

   Console

   ```
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Fri, 21 Jun 2019 03:38:45 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "name": "Scott Hunter"
     },
     {
       "id": 2,
       "name": "Scott Hanselman"
   ```

```
  },
  {
    "id": 3,
    "name": "Scott Guthrie"
  }
]

https://localhost:5001/people>
```

2. Retrieve a specific record by passing a parameter to the `get` command:

```
Console

https://localhost:5001/people> get 2
```

The preceding command displays the following output format:

```
Console

HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Fri, 21 Jun 2019 06:17:57 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 2,
    "name": "Scott Hanselman"
  }
]

https://localhost:5001/people>
```

Test HTTP POST requests

Synopsis

```
Console

post <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--
no-formatting] [--response] [--response:body] [--response:headers] [-s|--
streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{\"id\":2,\"name\":\"Cherry\"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

Indicates that no HTTP request body is needed.

Example

To issue an HTTP POST request:

1. Run the `post` command on an endpoint that supports it:

   Console

   ```
   https://localhost:5001/people> post -h Content-Type=application/json
   ```

   In the preceding command, the `Content-Type` HTTP request header is set to indicate a request body media type of JSON. The default text editor opens a *.tmp* file with a JSON template representing the HTTP request body. For example:

   JSON

   ```
   {
     "id": 0,
     "name": ""
   }
   ```

   > **Tip**
   >
   > To set the default text editor, see the **Set the default text editor** section.

2. Modify the JSON template to satisfy model validation requirements:

   JSON

   ```
   {
     "id": 0,
     "name": "Scott Addie"
   }
   ```

3. Save the *.tmp* file, and close the text editor. The following output appears in the command shell:

   Console

   ```
   HTTP/1.1 201 Created
   Content-Type: application/json; charset=utf-8
   Date: Thu, 27 Jun 2019 21:24:18 GMT
   ```

```
Location: https://localhost:5001/people/4
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 4,
  "name": "Scott Addie"
}

https://localhost:5001/people>
```

Test HTTP PUT requests

Synopsis

Console

```
put <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--no-formatting] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{\"id\":2,\"name\":\"Cherry\"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

  Indicates that no HTTP request body is needed.

Example

To issue an HTTP PUT request:

1. *Optional*: Run the `get` command to view the data before modifying it:

   Console

   ```
   https://localhost:5001/fruits> get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:07:32 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "data": "Apple"
     },
   ```

```
  {
    "id": 2,
    "data": "Orange"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]
```

2. Run the `put` command on an endpoint that supports it:

```
Console

https://localhost:5001/fruits> put 2 -h Content-Type=application/json
```

In the preceding command, the `Content-Type` HTTP request header is set to indicate a request body media type of JSON. The default text editor opens a *.tmp* file with a JSON template representing the HTTP request body. For example:

```
JSON

{
  "id": 0,
  "name": ""
}
```

> **Tip**
>
> To set the default text editor, see the **Set the default text editor** section.

3. Modify the JSON template to satisfy model validation requirements:

```
JSON

{
  "id": 2,
  "name": "Cherry"
}
```

4. Save the *.tmp* file, and close the text editor. The following output appears in the command shell:

```
Console
```

```
[main 2019-06-28T17:27:01.805Z] update#setState idle
HTTP/1.1 204 No Content
Date: Fri, 28 Jun 2019 17:28:21 GMT
Server: Kestrel
```

5. *Optional*: Issue a `get` command to see the modifications. For example, if you typed "Cherry" in the text editor, a `get` returns the following output:

Console

```
https://localhost:5001/fruits> get
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Sat, 22 Jun 2019 00:08:20 GMT
Server: Kestrel
Transfer-Encoding: chunked

[
  {
    "id": 1,
    "data": "Apple"
  },
  {
    "id": 2,
    "data": "Cherry"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]

https://localhost:5001/fruits>
```

Test HTTP DELETE requests

Synopsis

Console

```
delete <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Example

To issue an HTTP DELETE request:

1. *Optional*: Run the `get` command to view the data before modifying it:

   Console

   ```
   https://localhost:5001/fruits> get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:07:32 GMT
   Server: Kestrel
   Transfer-Encoding: chunked
   ```

```
[
  {
    "id": 1,
    "data": "Apple"
  },
  {
    "id": 2,
    "data": "Orange"
  },
  {
    "id": 3,
    "data": "Strawberry"
  }
]
```

2. Run the `delete` command on an endpoint that supports it:

   Console

   ```
   https://localhost:5001/fruits> delete 2
   ```

   The preceding command displays the following output format:

   Console

   ```
   HTTP/1.1 204 No Content
   Date: Fri, 28 Jun 2019 17:36:42 GMT
   Server: Kestrel
   ```

3. *Optional*: Issue a `get` command to see the modifications. In this example, a `get` returns the following output:

   Console

   ```
   https://localhost:5001/fruits> get
   HTTP/1.1 200 OK
   Content-Type: application/json; charset=utf-8
   Date: Sat, 22 Jun 2019 00:16:30 GMT
   Server: Kestrel
   Transfer-Encoding: chunked

   [
     {
       "id": 1,
       "data": "Apple"
     },
     {
       "id": 3,
       "data": "Strawberry"
     }
   ```

```
]

https://localhost:5001/fruits>
```

Test HTTP PATCH requests

Synopsis

Console

```
patch <PARAMETER> [-c|--content] [-f|--file] [-h|--header] [--no-body] [-F|--no-formatting] [--response] [--response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

  Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't

exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

- `-c|--content`

  Provides an inline HTTP request body. For example, `-c "{\"id\":2,\"name\":\"Cherry\"}"`.

- `-f|--file`

  Provides a path to a file containing the HTTP request body. For example, `-f "C:\request.json"`.

- `--no-body`

  Indicates that no HTTP request body is needed.

Test HTTP HEAD requests

Synopsis

Console

```
head <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Test HTTP OPTIONS requests

Synopsis

Console

```
options <PARAMETER> [-F|--no-formatting] [-h|--header] [--response] [--
response:body] [--response:headers] [-s|--streaming]
```

Arguments

`PARAMETER`

The route parameter, if any, expected by the associated controller action method.

Options

- `-F|--no-formatting`

  A flag whose presence suppresses HTTP response formatting.

- `-h|--header`

Sets an HTTP request header. The following two value formats are supported:
  - `{header}={value}`
  - `{header}:{value}`

- `--response:body`

  Specifies a file to which the HTTP response body should be written. For example, `--response:body "C:\response.json"`. The file is created if it doesn't exist.

- `--response:headers`

  Specifies a file to which the HTTP response headers should be written. For example, `--response:headers "C:\response.txt"`. The file is created if it doesn't exist.

- `-s|--streaming`

  A flag whose presence enables streaming of the HTTP response.

Set HTTP request headers

To set an HTTP request header, use one of the following approaches:

- Set inline with the HTTP request. For example:

  Console

  ```
  https://localhost:5001/people> post -h Content-Type=application/json
  ```

  With the preceding approach, each distinct HTTP request header requires its own `-h` option.

- Set before sending the HTTP request. For example:

  Console

  ```
  https://localhost:5001/people> set header Content-Type application/json
  ```

  When setting the header before sending a request, the header remains set for the duration of the command shell session. To clear the header, provide an empty value. For example:

  Console

```
https://localhost:5001/people> set header Content-Type
```

Test secured endpoints

The HttpRepl supports the testing of secured endpoints in the following ways:

- Via the default credentials of the logged in user.
- Through the use of HTTP request headers.

Default credentials

Consider a web API you're testing that's hosted in IIS and secured with Windows authentication. You want the credentials of the user running the tool to flow across to the HTTP endpoints being tested. To pass the default credentials of the logged in user:

1. Set the `httpClient.useDefaultCredentials` preference to `true`:

   Console

   ```
   pref set httpClient.useDefaultCredentials true
   ```

2. Exit and restart the tool before sending another request to the web API.

Default proxy credentials

Consider a scenario in which the web API you're testing is behind a proxy secured with Windows authentication. You want the credentials of the user running the tool to flow to the proxy. To pass the default credentials of the logged in user:

1. Set the `httpClient.proxy.useDefaultCredentials` preference to `true`:

   Console

   ```
   pref set httpClient.proxy.useDefaultCredentials true
   ```

2. Exit and restart the tool before sending another request to the web API.

HTTP request headers

Examples of supported authentication and authorization schemes include:

- basic authentication
- JWT bearer tokens
- digest authentication

For example, you can send a bearer token to an endpoint with the following command:

Console

```
set header Authorization "bearer <TOKEN VALUE>"
```

To access an Azure-hosted endpoint or to use the Azure REST API, you need a bearer token. Use the following steps to obtain a bearer token for your Azure subscription via the Azure CLI. The HttpRepl sets the bearer token in an HTTP request header. A list of Azure App Service Web Apps is retrieved.

1. Sign in to Azure:

   Azure CLI

   ```
   az login
   ```

2. Get your subscription ID with the following command:

   Azure CLI

   ```
   az account show --query id
   ```

3. Copy your subscription ID and run the following command:

   Azure CLI

   ```
   az account set --subscription "<SUBSCRIPTION ID>"
   ```

4. Get your bearer token with the following command:

   Azure CLI

   ```
   az account get-access-token --query accessToken
   ```

5. Connect to the Azure REST API via the HttpRepl:

   Console

```
httprepl https://management.azure.com
```

6. Set the `Authorization` HTTP request header:

```
Console

https://management.azure.com/> set header Authorization "bearer <ACCESS
TOKEN>"
```

7. Navigate to the subscription:

```
Console

https://management.azure.com/> cd subscriptions/<SUBSCRIPTION ID>
```

8. Get a list of your subscription's Azure App Service Web Apps:

```
Console

https://management.azure.com/subscriptions/{SUBSCRIPTION ID}> get
providers/Microsoft.Web/sites?api-version=2016-08-01
```

The following response is displayed:

```
Console

HTTP/1.1 200 OK
Cache-Control: no-cache
Content-Length: 35948
Content-Type: application/json; charset=utf-8
Date: Thu, 19 Sep 2019 23:04:03 GMT
Expires: -1
Pragma: no-cache
Strict-Transport-Security: max-age=31536000; includeSubDomains
X-Content-Type-Options: nosniff
x-ms-correlation-request-id: <em>xxxxxxxx-xxxx-xxxx-xxxx-
xxxxxxxxxxxx</em>
x-ms-original-request-ids: <em>xxxxxxxx-xxxx-xxxx-xxxx-
xxxxxxxxxxxx;xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx</em>
x-ms-ratelimit-remaining-subscription-reads: 11999
x-ms-request-id: xxxxxxxx-xxxx-xxxx-xxxx-xxxxxxxxxxxx
x-ms-routing-request-id: WESTUS:xxxxxxxxxxxxxxxx:xxxxxxxx-xxxx-xxxx-
xxxx-xxxxxxxxxx
{
  "value": [
    <AZURE RESOURCES LIST>
```

```
  ]
}
```

Toggle HTTP request display

By default, display of the HTTP request being sent is suppressed. It's possible to change the corresponding setting for the duration of the command shell session.

Enable request display

View the HTTP request being sent by running the `echo on` command. For example:

Console

```
https://localhost:5001/people> echo on
Request echoing is on
```

Subsequent HTTP requests in the current session display the request headers. For example:

Console

```
https://localhost:5001/people> post

[main 2019-06-28T18:50:11.930Z] update#setState idle
Request to https://localhost:5001...

POST /people HTTP/1.1
Content-Length: 41
Content-Type: application/json
User-Agent: HTTP-REPL

{
  "id": 0,
  "name": "Scott Addie"
}

Response from https://localhost:5001...

HTTP/1.1 201 Created
Content-Type: application/json; charset=utf-8
Date: Fri, 28 Jun 2019 18:50:21 GMT
Location: https://localhost:5001/people/4
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 4,
```

```
  "name": "Scott Addie"
}

https://localhost:5001/people>
```

Disable request display

Suppress display of the HTTP request being sent by running the `echo off` command. For example:

Console

```
https://localhost:5001/people> echo off
Request echoing is off
```

Run a script

If you frequently execute the same set of HttpRepl commands, consider storing them in a text file. Commands in the file take the same form as commands executed manually on the command line. The commands can be executed in a batched fashion using the `run` command. For example:

1. Create a text file containing a set of newline-delimited commands. To illustrate, consider a *people-script.txt* file containing the following commands:

   text

   ```
   set base https://localhost:5001
   ls
   cd People
   ls
   get 1
   ```

2. Execute the `run` command, passing in the text file's path. For example:

   Console

   ```
   https://localhost:5001/> run C:\http-repl-scripts\people-script.txt
   ```

   The following output appears:

   Console

```
https://localhost:5001/> set base https://localhost:5001
Using OpenAPI description at
https://localhost:5001/swagger/v1/swagger.json

https://localhost:5001/> ls
.        []
Fruits   [get|post]
People   [get|post]

https://localhost:5001/> cd People
/People    [get|post]

https://localhost:5001/People> ls
.      [get|post]
..     []
{id}   [get|put|delete]

https://localhost:5001/People> get 1
HTTP/1.1 200 OK
Content-Type: application/json; charset=utf-8
Date: Fri, 12 Jul 2019 19:20:10 GMT
Server: Kestrel
Transfer-Encoding: chunked

{
  "id": 1,
  "name": "Scott Hunter"
}

https://localhost:5001/People>
```

Clear the output

To remove all output written to the command shell by the HttpRepl tool, run the `clear` or `cls` command. To illustrate, imagine the command shell contains the following output:

Console

```
httprepl https://localhost:5001
(Disconnected)> set base "https://localhost:5001"
Using OpenAPI description at https://localhost:5001/swagger/v1/swagger.json

https://localhost:5001/> ls
.        []
Fruits   [get|post]
People   [get|post]
```

```
https://localhost:5001/>
```

Run the following command to clear the output:

Console

```
https://localhost:5001/> clear
```

After running the preceding command, the command shell contains only the following output:

Console

```
https://localhost:5001/>
```

HttpRepl telemetry

Article • 06/17/2024

The HttpRepl includes a telemetry feature that collects usage data. It's important that the HttpRepl team understands how the tool is used so it can be improved.

How to opt out

The HttpRepl telemetry feature is enabled by default. To opt out of the telemetry feature, set the `DOTNET_HTTPREPL_TELEMETRY_OPTOUT` environment variable to `1` or `true`.

Disclosure

The HttpRepl displays text similar to the following when you first run the tool. Text may vary slightly depending on the version of the tool you're running. This "first run" experience is how Microsoft notifies you about data collection.

Console

```
Telemetry
---------
The .NET tools collect usage data in order to help us improve your
experience. It is collected by Microsoft and shared with the community. You
can opt-out of telemetry by setting the DOTNET_HTTPREPL_TELEMETRY_OPTOUT
environment variable to '1' or 'true' using your favorite shell.
```

To suppress the "first run" experience text, set the `DOTNET_HTTPREPL_SKIP_FIRST_TIME_EXPERIENCE` environment variable to `1` or `true`.

Data points

The telemetry feature doesn't:

- Collect personal data, such as usernames, email addresses, or URLs.
- Scan your HTTP requests or responses.

The data is sent securely to Microsoft servers and held under restricted access.

Protecting your privacy is important to us. If you suspect the telemetry feature is collecting sensitive data or the data is being insecurely or inappropriately handled, take one of the following actions:

- File an issue in the dotnet/httprepl repository.
- Send an email to dotnet@microsoft.com for investigation.

The telemetry feature collects the following data.

Expand table

.NET SDK versions	Data
>=5.0	Timestamp of invocation.
>=5.0	Three-octet IP address used to determine the geographical location.
>=5.0	Operating system and version.
>=5.0	Runtime ID (RID) the tool is running on.
>=5.0	Whether the tool is running in a container.
>=5.0	Hashed Media Access Control (MAC) address: a cryptographically (SHA256) hashed and unique ID for a machine.
>=5.0	Kernel version.
>=5.0	HttpRepl version.
>=5.0	Whether the tool was started with `help`, `run`, or `connect` arguments. Actual argument values aren't collected.
>=5.0	Command invoked (for example, `get`) and whether it succeeded.
>=5.0	For the `connect` command, whether the `root`, `base`, or `openapi` arguments were supplied. Actual argument values aren't collected.
>=5.0	For the `pref` command, whether a `get` or `set` was issued and which preference was accessed. If not a well-known preference, the name is hashed. The value isn't collected.
>=5.0	For the `set header` command, the header name being set. If not a well-known header, the name is hashed. The value isn't collected.
>=5.0	For the `connect` command, whether a special case for `dotnet new webapi` was used and, whether it was bypassed via preference.
>=5.0	For all HTTP commands (for example, GET, POST, PUT), whether each of the options was specified. The values of the options aren't collected.

Minimal APIs overview

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Minimal APIs are a simplified approach for building fast HTTP APIs with ASP.NET Core. You can build fully functioning REST endpoints with minimal code and configuration. Skip traditional scaffolding and avoid unnecessary controllers by fluently declaring API routes and actions. For example, the following code creates an API at the root of the web app that returns the text, `"Hello World!"`.

C#

```
var app = WebApplication.Create(args);

app.MapGet("/", () => "Hello World!");

app.Run();
```

Most APIs accept parameters as part of the route.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/users/{userId}/books/{bookId}",
    (int userId, int bookId) => $"The user id is {userId} and book id is
{bookId}");

app.Run();
```

That's all it takes to get started, but it's not all that's available. Minimal APIs support the configuration and customization needed to scale to multiple APIs, handle complex routes, apply authorization rules, and control the content of API responses. A good place to get started is Tutorial: Create a minimal API with ASP.NET Core.

By Rick Anderson and Tom Dykstra

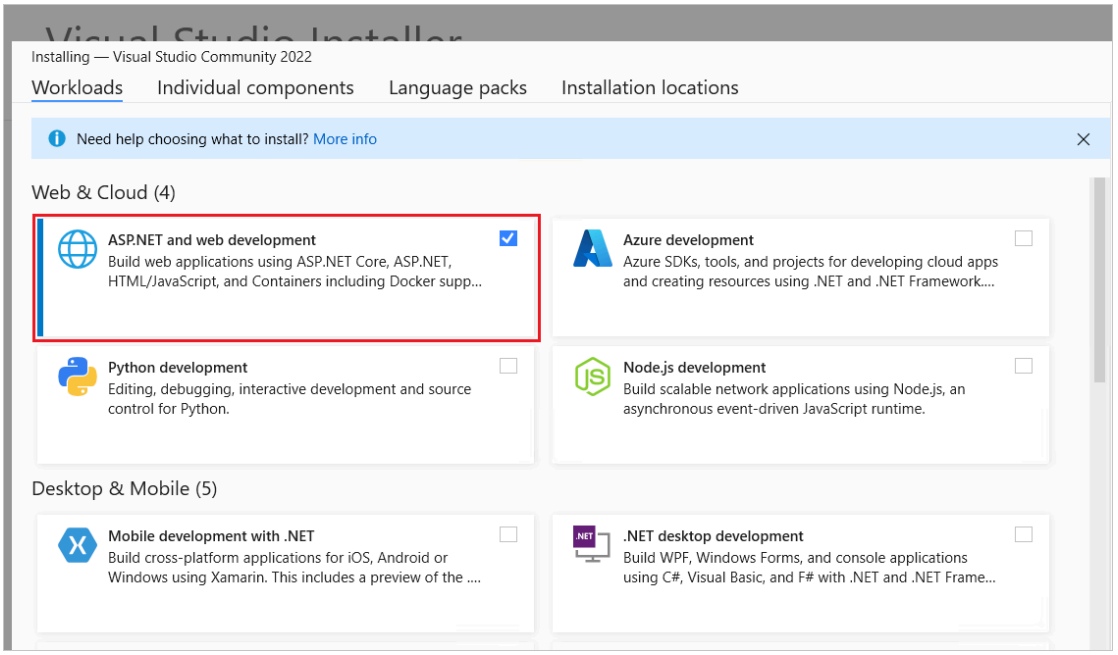
Minimal APIs are architected to create HTTP APIs with minimal dependencies. They're ideal for microservices and apps that want to include only the minimum files, features, and dependencies in ASP.NET Core.

This tutorial teaches the basics of building a minimal API with ASP.NET Core. Another approach to creating APIs in ASP.NET Core is to use controllers. For help with choosing between minimal APIs and controller-based APIs, see APIs overview. For a tutorial on creating an API project based on controllers that contains more features, see Create a web API.

Overview

This tutorial creates the following API:

Expand table

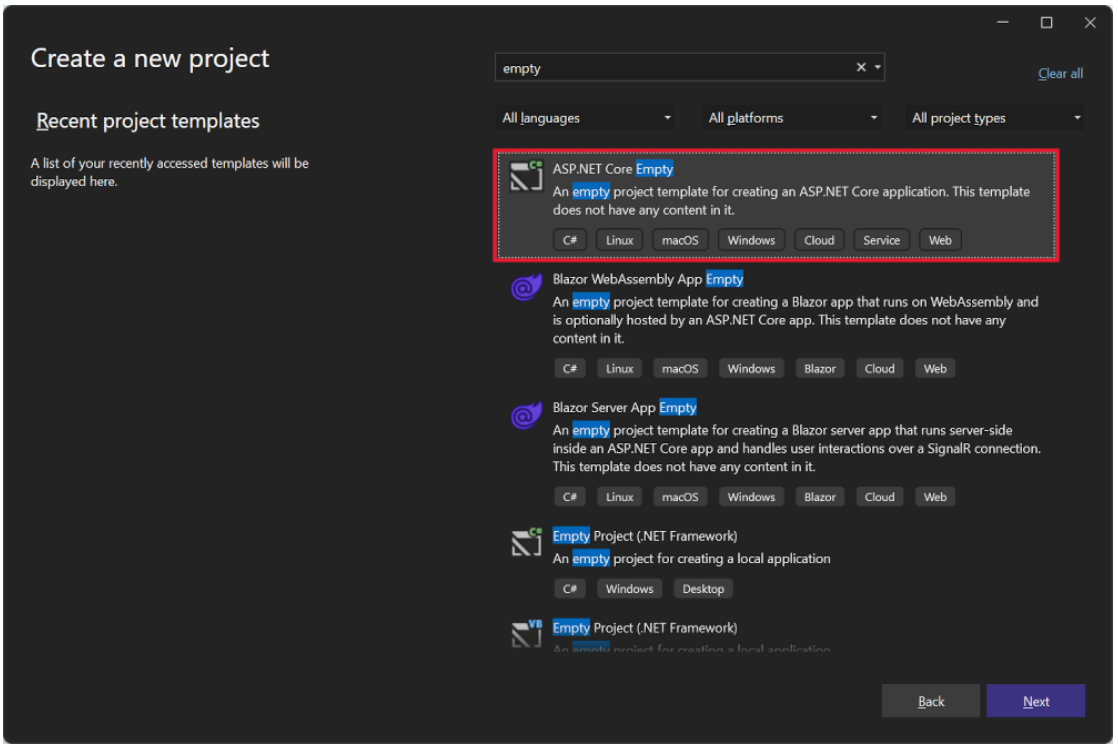


API	Description	Request body	Response body
`GET /todoitems`	Get all to-do items	None	Array of to-do items
`GET /todoitems/complete`	Get completed to-do items	None	Array of to-do items
`GET /todoitems/{id}`	Get an item by ID	None	To-do item
`POST /todoitems`	Add a new item	To-do item	To-do item
`PUT /todoitems/{id}`	Update an existing item	To-do item	None

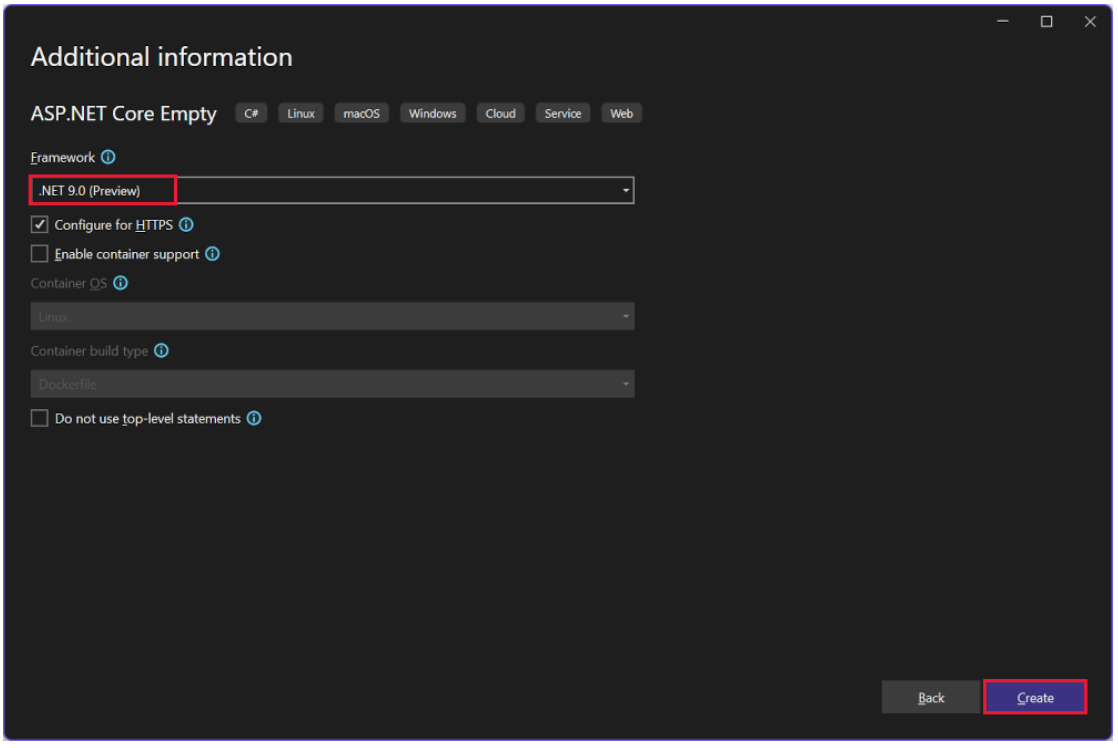
API	Description	Request body	Response body
`DELETE /todoitems/{id}`	Delete an item	None	None

Prerequisites

Visual Studio



- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create an API project

Visual Studio

- Start Visual Studio 2022 and select **Create a new project**.
- In the **Create a new project** dialog:
  - Enter `Empty` in the **Search for templates** search box.
  - Select the **ASP.NET Core Empty** template and select **Next**.

- Name the project *TodoApi* and select **Next**.
- In the **Additional information** dialog:
  - Select **.NET 9.0 (Preview)**
  - Uncheck **Do not use top-level statements**
  - Select **Create**

Examine the code

The `Program.cs` file contains the following code:

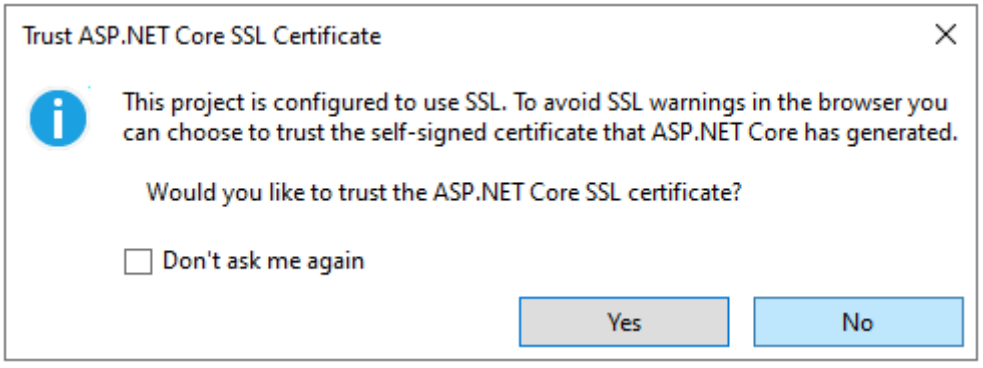
C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

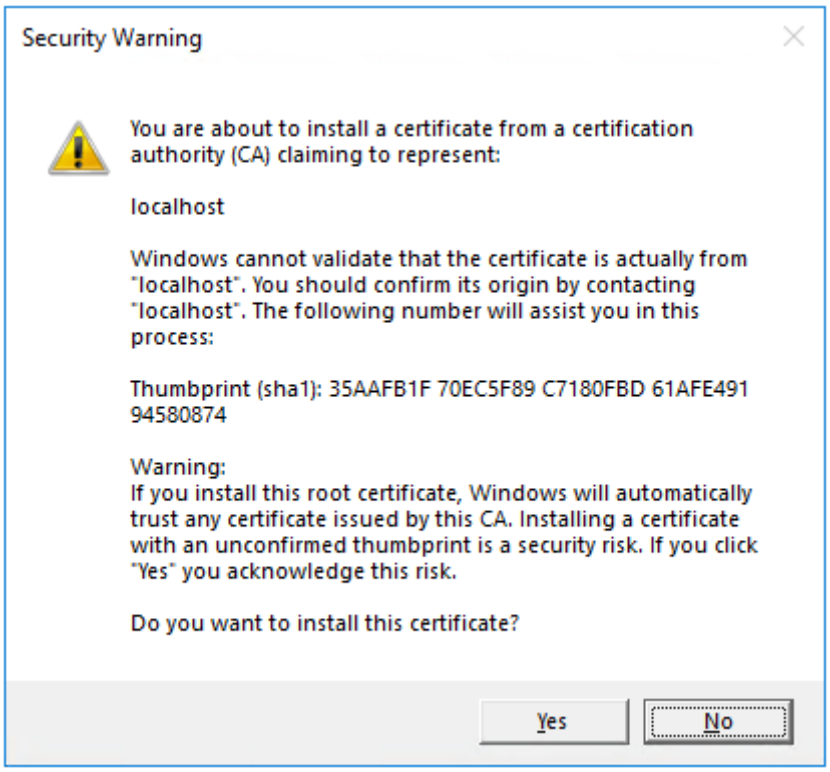
The preceding code:



- Creates a WebApplicationBuilder and a WebApplication with preconfigured defaults.
- Creates an HTTP GET endpoint `/` that returns `Hello World!`:

Run the app

Visual Studio



Press Ctrl+F5 to run without the debugger.

Visual Studio displays the following dialog:

Select **Yes** if you trust the IIS Express SSL certificate.

The following dialog is displayed:

Select **Yes** if you agree to trust the development certificate.

For information on trusting the Firefox browser, see Firefox SEC_ERROR_INADEQUATE_KEY_USAGE certificate error.

Visual Studio launches the Kestrel web server and opens a browser window.

`Hello World!` is displayed in the browser. The `Program.cs` file contains a minimal but complete app.

Close the browser window.

Add NuGet packages

NuGet packages must be added to support the database and diagnostics used in this tutorial.

Visual Studio

- From the **Tools** menu, select **NuGet Package Manager** > **Manage NuGet Packages for Solution**.
- Select the **Browse** tab.
- Select **Include Prelease**.
- Enter **Microsoft.EntityFrameworkCore.InMemory** in the search box, and then select `Microsoft.EntityFrameworkCore.InMemory`.

- Select the **Project** checkbox in the right pane and then select **Install**.
- Follow the preceding instructions to add the `Microsoft.AspNetCore.Diagnostics.EntityFrameworkCore` package.

The model and database context classes

- In the project folder, create a file named `Todo.cs` with the following code:

C#

```
public class Todo
{
    public int Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
```

The preceding code creates the model for this app. A *model* is a class that represents data that the app manages.

- Create a file named `TodoDb.cs` with the following code:

C#

```
using Microsoft.EntityFrameworkCore;

class TodoDb : DbContext
{
    public TodoDb(DbContextOptions<TodoDb> options)
        : base(options) { }

    public DbSet<Todo> Todos => Set<Todo>();
}
```

The preceding code defines the *database context*, which is the main class that coordinates Entity Framework functionality for a data model. This class derives from the Microsoft.EntityFrameworkCore.DbContext class.

Add the API code

- Replace the contents of the `Program.cs` file with the following code:

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

app.MapGet("/todoitems", async (TodoDb db) =>
    await db.Todos.ToListAsync());

app.MapGet("/todoitems/complete", async (TodoDb db) =>
    await db.Todos.Where(t => t.IsComplete).ToListAsync());

app.MapGet("/todoitems/{id}", async (int id, TodoDb db) =>
    await db.Todos.FindAsync(id)
        is Todo todo
            ? Results.Ok(todo)
            : Results.NotFound());

app.MapPost("/todoitems", async (Todo todo, TodoDb db) =>
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
});

app.MapPut("/todoitems/{id}", async (int id, Todo inputTodo, TodoDb db) =>
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
});

app.MapDelete("/todoitems/{id}", async (int id, TodoDb db) =>
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return Results.NoContent();
    }

    return Results.NotFound();
});
```

```
app.Run();
```

The following highlighted code adds the database context to the dependency injection (DI) container and enables displaying database-related exceptions:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();
```

The DI container provides access to the database context and other services.

Visual Studio

This tutorial uses Endpoints Explorer and .http files to test the API.

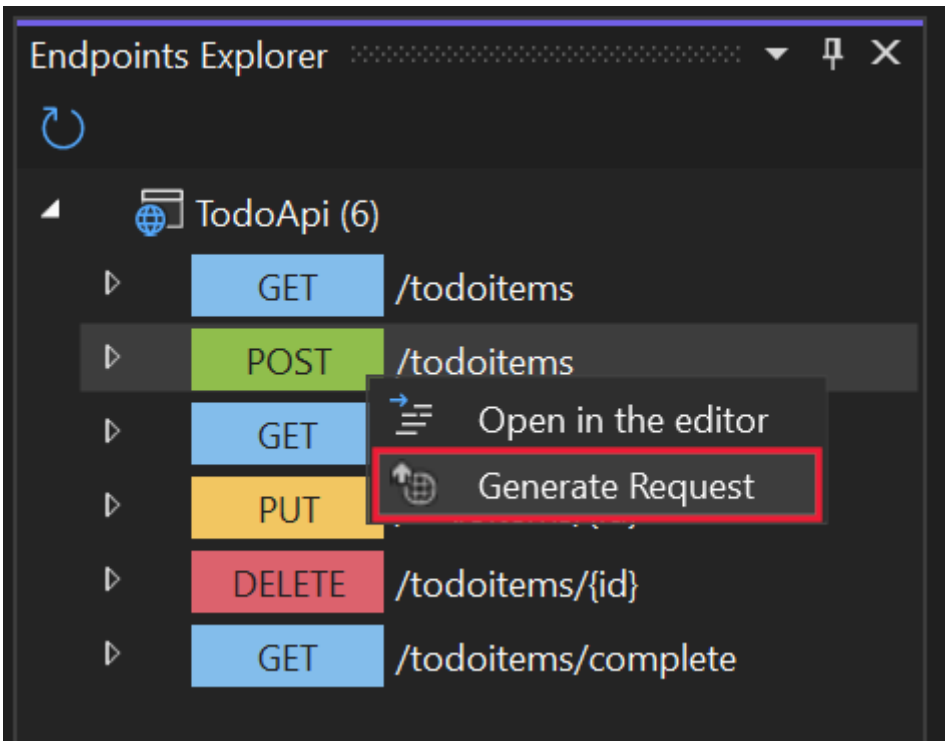
Test posting data

The following code in `Program.cs` creates an HTTP POST endpoint `/todoitems` that adds data to the in-memory database:

C#

```
app.MapPost("/todoitems", async (Todo todo, TodoDb db) =>
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
});
```



Run the app. The browser displays a 404 error because there's no longer a `/` endpoint.

The POST endpoint will be used to add data to the app.

Visual Studio

- Select **View** > **Other Windows** > **Endpoints Explorer**.

- Right-click the **POST** endpoint and select **Generate request**.

A new file is created in the project folder named `TodoApi.http`, with contents similar to the following example:

```
@TodoApi_HostAddress = https://localhost:7031

Post {{TodoApi_HostAddress}}/todoitems

###
```

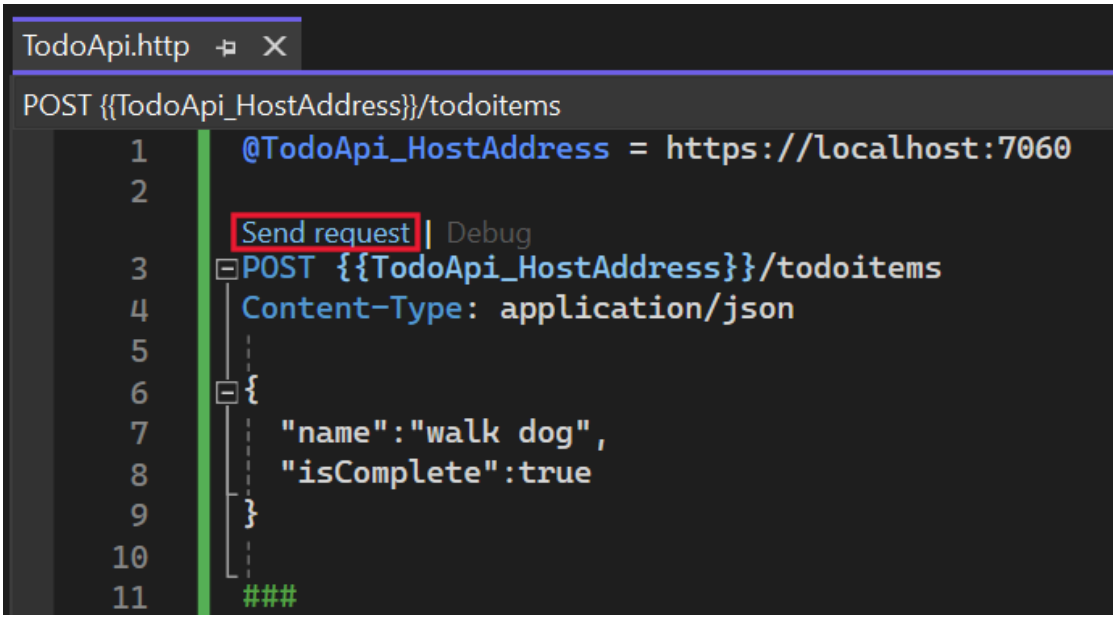
  - The first line creates a variable that is used for all of the endpoints.
  - The next line defines a POST request.
  - The triple hashtag (`###`) line is a request delimiter: what comes after it is for a different request.

- The POST request needs headers and a body. To define those parts of the request, add the following lines immediately after the POST request line:

```
Content-Type: application/json

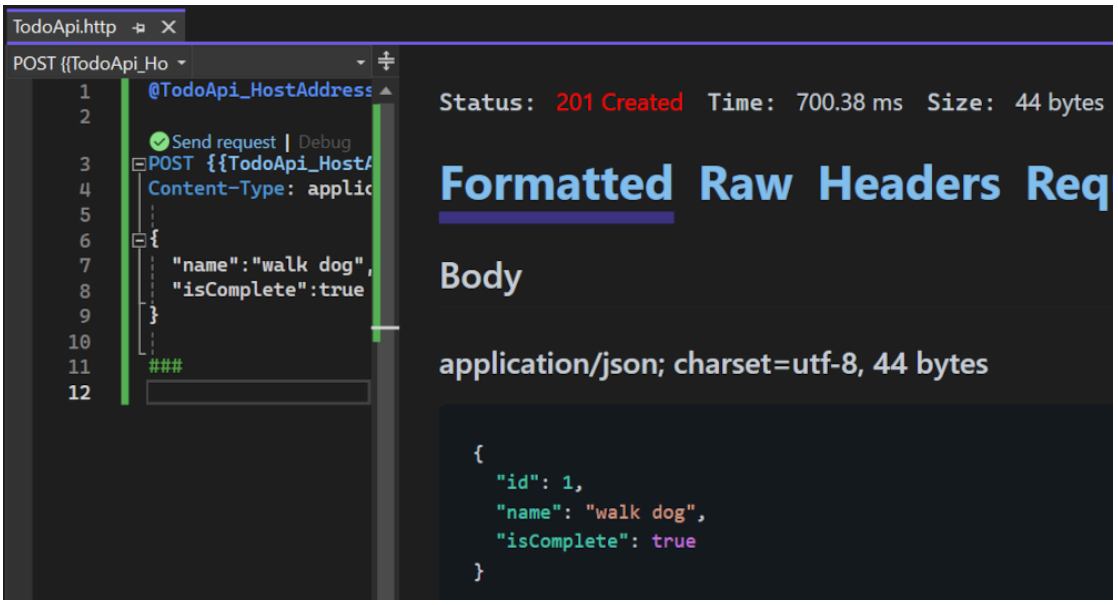
{
  "name":"walk dog",
  "isComplete":true
}
```

The preceding code adds a Content-Type header and a JSON request body. The TodoApi.http file should now look like the following example, but with your port number:



```
@TodoApi_HostAddress = https://localhost:7057

Post {{TodoApi_HostAddress}}/todoitems
Content-Type: application/json



{
  "name":"walk dog",
  "isComplete":true
}

###
```

- Run the app.
- Select the **Send request** link that is above the `POST` request line.

The POST request is sent to the app and the response is displayed in the **Response** pane.

Examine the GET endpoints

The sample app implements several GET endpoints by calling `MapGet`:

Expand table

API	Description	Request body	Response body
`GET /todoitems`	Get all to-do items	None	Array of to-do items
`GET /todoitems/complete`	Get all completed to-do items	None	Array of to-do items
`GET /todoitems/{id}`	Get an item by ID	None	To-do item

C#

```
app.MapGet("/todoitems", async (TodoDb db) =>
    await db.Todos.ToListAsync());

app.MapGet("/todoitems/complete", async (TodoDb db) =>
    await db.Todos.Where(t => t.IsComplete).ToListAsync());

app.MapGet("/todoitems/{id}", async (int id, TodoDb db) =>
    await db.Todos.FindAsync(id)
        is Todo todo
            ? Results.Ok(todo)
            : Results.NotFound());
```

Test the GET endpoints

Visual Studio

Test the app by calling the `GET` endpoints from a browser or by using **Endpoints Explorer**. The following steps are for **Endpoints Explorer**.

- In **Endpoints Explorer**, right-click the first **GET** endpoint, and select **Generate request**.

  The following content is added to the `TodoApi.http` file:

  ```
  Get {{TodoApi_HostAddress}}/todoitems

  ###
  ```

- Select the **Send request** link that is above the new `GET` request line.

  The GET request is sent to the app and the response is displayed in the **Response** pane.

- The response body is similar to the following JSON:

  JSON

  ```
  [
    {
      "id": 1,
      "name": "walk dog",
      "isComplete": true
    }
  ]
  ```

- In **Endpoints Explorer**, right-click the `/todoitems/{id}` **GET** endpoint and select **Generate request**. The following content is added to the `TodoApi.http` file:

  ```
  GET {{TodoApi_HostAddress}}/todoitems/{id}

  ###
  ```

- Replace `{id}` with `1`.

- Select the **Send request** link that is above the new GET request line.

  The GET request is sent to the app and the response is displayed in the **Response** pane.

- The response body is similar to the following JSON:

  ```
  JSON

  {
    "id": 1,
    "name": "walk dog",
    "isComplete": true
  }
  ```

This app uses an in-memory database. If the app is restarted, the GET request doesn't return any data. If no data is returned, POST data to the app and try the GET request again.

Return values

ASP.NET Core automatically serializes the object to JSON and writes the JSON into the body of the response message. The response code for this return type is 200 OK, assuming there are no unhandled exceptions. Unhandled exceptions are translated into 5xx errors.

The return types can represent a wide range of HTTP status codes. For example, `GET /todoitems/{id}` can return two different status values:

- If no item matches the requested ID, the method returns a 404 status NotFound error code.
- Otherwise, the method returns 200 with a JSON response body. Returning `item` results in an HTTP 200 response.

Examine the PUT endpoint

The sample app implements a single PUT endpoint using `MapPut`:

```
C#

app.MapPut("/todoitems/{id}", async (int id, Todo inputTodo, TodoDb db) =>
{
```

```
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
});
```

This method is similar to the `MapPost` method, except it uses HTTP PUT. A successful response returns 204 (No Content). According to the HTTP specification, a PUT request requires the client to send the entire updated entity, not just the changes. To support partial updates, use HTTP PATCH.

Test the PUT endpoint

This sample uses an in-memory database that must be initialized each time the app is started. There must be an item in the database before you make a PUT call. Call GET to ensure there's an item in the database before making a PUT call.

Update the to-do item that has `Id = 1` and set its name to `"feed fish"`.

Visual Studio

- In **Endpoints Explorer**, right-click the **PUT** endpoint, and select **Generate request**.

  The following content is added to the `TodoApi.http` file:

  ```
  Put {{TodoApi_HostAddress}}/todoitems/{id}

  ###
  ```

- In the PUT request line, replace `{id}` with `1`.
- Add the following lines immediately after the PUT request line:

  ```
  ```

```
Content-Type: application/json

{
  "name": "feed fish",
  "isComplete": false
}
```

The preceding code adds a Content-Type header and a JSON request body.

- Select the **Send request** link that is above the new PUT request line.

  The PUT request is sent to the app and the response is displayed in the **Response** pane. The response body is empty, and the status code is 204.

Examine and test the DELETE endpoint

The sample app implements a single DELETE endpoint using `MapDelete`:

C#

```
app.MapDelete("/todoitems/{id}", async (int id, TodoDb db) =>
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return Results.NoContent();
    }

    return Results.NotFound();
});
```

Visual Studio

- In **Endpoints Explorer**, right-click the **DELETE** endpoint and select **Generate request**.

  A DELETE request is added to `TodoApi.http`.

- Replace `{id}` in the DELETE request line with `1`. The DELETE request should look like the following example:

  ```
  
  ```

```
DELETE {{TodoApi_HostAddress}}/todoitems/1

###
```

- Select the **Send request** link for the DELETE request.

  The DELETE request is sent to the app and the response is displayed in the **Response** pane. The response body is empty, and the status code is 204.

Use the MapGroup API

The sample app code repeats the `todoitems` URL prefix each time it sets up an endpoint. APIs often have groups of endpoints with a common URL prefix, and the MapGroup method is available to help organize such groups. It reduces repetitive code and allows for customizing entire groups of endpoints with a single call to methods like RequireAuthorization and WithMetadata.

Replace the contents of `Program.cs` with the following code:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

var todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", async (TodoDb db) =>
    await db.Todos.ToListAsync());

todoItems.MapGet("/complete", async (TodoDb db) =>
    await db.Todos.Where(t => t.IsComplete).ToListAsync());

todoItems.MapGet("/{id}", async (int id, TodoDb db) =>
    await db.Todos.FindAsync(id)
        is Todo todo
            ? Results.Ok(todo)
            : Results.NotFound());
```

```
todoItems.MapPost("/", async (Todo todo, TodoDb db) =>
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
});

todoItems.MapPut("/{id}", async (int id, Todo inputTodo, TodoDb db) =>
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
});

todoItems.MapDelete("/{id}", async (int id, TodoDb db) =>
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return Results.NoContent();
    }

    return Results.NotFound();
});

app.Run();
```

The preceding code has the following changes:

- Adds `var todoItems = app.MapGroup("/todoitems");` to set up the group using the URL prefix `/todoitems`.
- Changes all the `app.Map<HttpVerb>` methods to `todoItems.Map<HttpVerb>`.
- Removes the URL prefix `/todoitems` from the `Map<HttpVerb>` method calls.

Test the endpoints to verify that they work the same.

Use the TypedResults API

Returning TypedResults rather than Results has several advantages, including testability and automatically returning the response type metadata for OpenAPI to describe the

endpoint. For more information, see TypedResults vs Results.

The `Map<HttpVerb>` methods can call route handler methods instead of using lambdas. To see an example, update *Program.cs* with the following code:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

var todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", GetAllTodos);
todoItems.MapGet("/complete", GetCompleteTodos);
todoItems.MapGet("/{id}", GetTodo);
todoItems.MapPost("/", CreateTodo);
todoItems.MapPut("/{id}", UpdateTodo);
todoItems.MapDelete("/{id}", DeleteTodo);

app.Run();

static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.ToArrayAsync());
}

static async Task<IResult> GetCompleteTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.Where(t =>
t.IsComplete).ToListAsync());
}

static async Task<IResult> GetTodo(int id, TodoDb db)
{
    return await db.Todos.FindAsync(id)
        is Todo todo
            ? TypedResults.Ok(todo)
            : TypedResults.NotFound();
}

static async Task<IResult> CreateTodo(Todo todo, TodoDb db)
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();
```

```
    return TypedResults.Created($"/todoitems/{todo.Id}", todo);
}

static async Task<IResult> UpdateTodo(int id, Todo inputTodo, TodoDb db)
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return TypedResults.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return TypedResults.NoContent();
}

static async Task<IResult> DeleteTodo(int id, TodoDb db)
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return TypedResults.NoContent();
    }

    return TypedResults.NotFound();
}
```

The `Map<HttpVerb>` code now calls methods instead of lambdas:

C#

```
var todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", GetAllTodos);
todoItems.MapGet("/complete", GetCompleteTodos);
todoItems.MapGet("/{id}", GetTodo);
todoItems.MapPost("/", CreateTodo);
todoItems.MapPut("/{id}", UpdateTodo);
todoItems.MapDelete("/{id}", DeleteTodo);
```

These methods return objects that implement IResult and are defined by TypedResults:

C#

```
static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.ToArrayAsync());
}
```

```
static async Task<IResult> GetCompleteTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.Where(t =>
t.IsComplete).ToListAsync());
}

static async Task<IResult> GetTodo(int id, TodoDb db)
{
    return await db.Todos.FindAsync(id)
        is Todo todo
            ? TypedResults.Ok(todo)
            : TypedResults.NotFound();
}

static async Task<IResult> CreateTodo(Todo todo, TodoDb db)
{
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return TypedResults.Created($"/todoitems/{todo.Id}", todo);
}

static async Task<IResult> UpdateTodo(int id, Todo inputTodo, TodoDb db)
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return TypedResults.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return TypedResults.NoContent();
}

static async Task<IResult> DeleteTodo(int id, TodoDb db)
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return TypedResults.NoContent();
    }

    return TypedResults.NotFound();
}
```

Unit tests can call these methods and test that they return the correct type. For example, if the method is `GetAllTodos`:

```
C#
```

```
static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.ToArrayAsync());
}
```

Unit test code can verify that an object of type Ok<Todo[]> is returned from the handler method. For example:

C#

```
public async Task GetAllTodos_ReturnsOkOfTodosResult()
{
    // Arrange
    var db = CreateDbContext();

    // Act
    var result = await TodosApi.GetAllTodos(db);

    // Assert: Check for the correct returned type
    Assert.IsType<Ok<Todo[]>>(result);
}
```

Prevent over-posting

Currently the sample app exposes the entire `Todo` object. Production apps In production applications, a subset of the model is often used to restrict the data that can be input and returned. There are multiple reasons behind this and security is a major one. The subset of a model is usually referred to as a Data Transfer Object (DTO), input model, or view model. **DTO** is used in this article.

A DTO can be used to:

- Prevent over-posting.
- Hide properties that clients aren't supposed to view.
- Omit some properties to reduce payload size.
- Flatten object graphs that contain nested objects. Flattened object graphs can be more convenient for clients.

To demonstrate the DTO approach, update the `Todo` class to include a secret field:

C#

```
public class Todo
{
    public int Id { get; set; }
```

```
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
    public string? Secret { get; set; }
}
```

The secret field needs to be hidden from this app, but an administrative app could choose to expose it.

Verify you can post and get the secret field.

Create a file named `TodoItemDTO.cs` with the following code:

C#

```
public class TodoItemDTO
{
    public int Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }

    public TodoItemDTO() { }
    public TodoItemDTO(Todo todoItem) =>
    (Id, Name, IsComplete) = (todoItem.Id, todoItem.Name,
todoItem.IsComplete);
}
```

Replace the contents of the `Program.cs` file with the following code to use this DTO model:

Visual Studio

C#

```
using Microsoft.EntityFrameworkCore;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
var app = builder.Build();

RouteGroupBuilder todoItems = app.MapGroup("/todoitems");

todoItems.MapGet("/", GetAllTodos);
todoItems.MapGet("/complete", GetCompleteTodos);
todoItems.MapGet("/{id}", GetTodo);
todoItems.MapPost("/", CreateTodo);
todoItems.MapPut("/{id}", UpdateTodo);
todoItems.MapDelete("/{id}", DeleteTodo);
```

```
app.Run();

static async Task<IResult> GetAllTodos(TodoDb db)
{
    return TypedResults.Ok(await db.Todos.Select(x => new
TodoItemDTO(x)).ToArrayAsync());
}

static async Task<IResult> GetCompleteTodos(TodoDb db) {
    return TypedResults.Ok(await db.Todos.Where(t =>
t.IsComplete).Select(x => new TodoItemDTO(x)).ToListAsync());
}

static async Task<IResult> GetTodo(int id, TodoDb db)
{
    return await db.Todos.FindAsync(id)
        is Todo todo
            ? TypedResults.Ok(new TodoItemDTO(todo))
            : TypedResults.NotFound();
}

static async Task<IResult> CreateTodo(TodoItemDTO todoItemDTO, TodoDb
db)
{
    var todoItem = new Todo
    {
        IsComplete = todoItemDTO.IsComplete,
        Name = todoItemDTO.Name
    };

    db.Todos.Add(todoItem);
    await db.SaveChangesAsync();

    todoItemDTO = new TodoItemDTO(todoItem);

    return TypedResults.Created($"/todoitems/{todoItem.Id}",
todoItemDTO);
}

static async Task<IResult> UpdateTodo(int id, TodoItemDTO todoItemDTO,
TodoDb db)
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return TypedResults.NotFound();

    todo.Name = todoItemDTO.Name;
    todo.IsComplete = todoItemDTO.IsComplete;

    await db.SaveChangesAsync();

    return TypedResults.NoContent();
}
```

```
static async Task<IResult> DeleteTodo(int id, TodoDb db)
{
    if (await db.Todos.FindAsync(id) is Todo todo)
    {
        db.Todos.Remove(todo);
        await db.SaveChangesAsync();
        return TypedResults.NoContent();
    }

    return TypedResults.NotFound();
}
```

Verify you can post and get all fields except the secret field.

Troubleshooting with the completed sample

If you run into a problem you can't resolve, compare your code to the completed project. View or download completed project (how to download).

Next steps

- Configure JSON serialization options.
- Handle errors and exceptions: The developer exception page is enabled by default in the development environment for minimal API apps. For information about how to handle errors and exceptions, see Handle errors in ASP.NET Core APIs.
- For an example of testing a minimal API app, see this GitHub sample.
- OpenAPI support in minimal APIs.
- Quickstart: Publish to Azure.
- Organizing ASP.NET Core Minimal APIs.

>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

This document:

- Provides a quick reference for minimal APIs.
- Is intended for experienced developers. For an introduction, see Tutorial: Create a minimal API with ASP.NET Core.

The minimal APIs consist of:

- WebApplication and WebApplicationBuilder
- Route Handlers

`WebApplication`

The following code is generated by an ASP.NET Core template:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The preceding code can be created via `dotnet new web` on the command line or selecting the Empty Web template in Visual Studio.

The following code creates a WebApplication (`app`) without explicitly creating a WebApplicationBuilder:

```
C#
```

```
var app = WebApplication.Create(args);

app.MapGet("/", () => "Hello World!");

app.Run();
```

WebApplication.Create initializes a new instance of the WebApplication class with preconfigured defaults.

Working with ports

When a web app is created with Visual Studio or `dotnet new`, a `Properties/launchSettings.json` file is created that specifies the ports the app responds to. In the port setting samples that follow, running the app from Visual Studio returns an error dialog `Unable to connect to web server 'AppName'`. Visual Studio returns an error because it's expecting the port specified in `Properties/launchSettings.json`, but the app is using the port specified by `app.Run("http://localhost:3000")`. Run the following port changing samples from the command line.

The following sections set the port the app responds to.

C#

```
var app = WebApplication.Create(args);

app.MapGet("/", () => "Hello World!");

app.Run("http://localhost:3000");
```

In the preceding code, the app responds to port `3000`.

Multiple ports

In the following code, the app responds to port `3000` and `4000`.

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("http://localhost:3000");
app.Urls.Add("http://localhost:4000");

app.MapGet("/", () => "Hello World");
```

```
app.Run();
```

Set the port from the command line

The following command makes the app respond to port `7777`:

.NET CLI

```
dotnet run --urls="https://localhost:7777"
```

If the Kestrel endpoint is also configured in the `appsettings.json` file, the `appsettings.json` file specified URL is used. For more information, see Kestrel endpoint configuration

Read the port from environment

The following code reads the port from the environment:

C#

```
var app = WebApplication.Create(args);

var port = Environment.GetEnvironmentVariable("PORT") ?? "3000";

app.MapGet("/", () => "Hello World");

app.Run($"http://localhost:{port}");
```

The preferred way to set the port from the environment is to use the `ASPNETCORE_URLS` environment variable, which is shown in the following section.

Set the ports via the ASPNETCORE_URLS environment variable

The `ASPNETCORE_URLS` environment variable is available to set the port:

```
ASPNETCORE_URLS=http://localhost:3000
```

`ASPNETCORE_URLS` supports multiple URLs:

```
ASPNETCORE_URLS=http://localhost:3000;https://localhost:5000
```

Listen on all interfaces

The following samples demonstrate listening on all interfaces

http://*:3000

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("http://*:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

http://+:3000

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("http://+:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

`http://0.0.0.0:3000`

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("http://0.0.0.0:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Listen on all interfaces using ASPNETCORE_URLS

The preceding samples can use `ASPNETCORE_URLS`

```
ASPNETCORE_URLS=http://*:3000;https://+:5000;http://0.0.0.0:5005
```

Listen on all interfaces using ASPNETCORE_HTTPS_PORTS

The preceding samples can use `ASPNETCORE_HTTPS_PORTS` and `ASPNETCORE_HTTP_PORTS`.

```
ASPNETCORE_HTTP_PORTS=3000;5005
ASPNETCORE_HTTPS_PORTS=5000
```

For more information, see Configure endpoints for the ASP.NET Core Kestrel web server

Specify HTTPS with development certificate

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

For more information on the development certificate, see Trust the ASP.NET Core HTTPS development certificate on Windows and macOS.

Specify HTTPS using a custom certificate

The following sections show how to specify the custom certificate using the `appsettings.json` file and via configuration.

Specify the custom certificate with `appsettings.json`

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
  "Kestrel": {
    "Certificates": {
      "Default": {
        "Path": "cert.pem",
        "KeyPath": "key.pem"
      }
    }
  }
}
```

Specify the custom certificate via configuration

C#

```
var builder = WebApplication.CreateBuilder(args);

// Configure the cert and the key
builder.Configuration["Kestrel:Certificates:Default:Path"] = "cert.pem";
builder.Configuration["Kestrel:Certificates:Default:KeyPath"] = "key.pem";

var app = builder.Build();

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Use the certificate APIs

C#

```
using System.Security.Cryptography.X509Certificates;

var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(options =>
{
    options.ConfigureHttpsDefaults(httpsOptions =>
    {
        var certPath = Path.Combine(builder.Environment.ContentRootPath,
```

```
"cert.pem");
        var keyPath = Path.Combine(builder.Environment.ContentRootPath,
"key.pem");

        httpsOptions.ServerCertificate =
X509Certificate2.CreateFromPemFile(certPath,
                                           keyPath);
    });
});

var app = builder.Build();

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Read the environment

C#

```
var app = WebApplication.Create(args);

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/oops");
}

app.MapGet("/", () => "Hello World");
app.MapGet("/oops", () => "Oops! An error happened.");

app.Run();
```

For more information using the environment, see Use multiple environments in ASP.NET Core

Configuration

The following code reads from the configuration system:

C#

```
var app = WebApplication.Create(args);

var message = app.Configuration["HelloKey"] ?? "Config failed!";

app.MapGet("/", () => message);
```

```
app.Run();
```

For more information, see Configuration in ASP.NET Core

Logging

The following code writes a message to the log on application startup:

C#

```
var app = WebApplication.Create(args);

app.Logger.LogInformation("The app started");

app.MapGet("/", () => "Hello World");

app.Run();
```

For more information, see Logging in .NET Core and ASP.NET Core

Access the Dependency Injection (DI) container

The following code shows how to get services from the DI container during application startup:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddScoped<SampleService>();

var app = builder.Build();

app.MapControllers();

using (var scope = app.Services.CreateScope())
{
    var sampleService =
scope.ServiceProvider.GetRequiredService<SampleService>();
    sampleService.DoSomething();
}

app.Run();
```

The following code shows how to access keys from the DI container using the [FromKeyedServices] attribute:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddKeyedSingleton<ICache, BigCache>("big");
builder.Services.AddKeyedSingleton<ICache, SmallCache>("small");

var app = builder.Build();

app.MapGet("/big", ([FromKeyedServices("big")] ICache bigCache) =>
bigCache.Get("date"));

app.MapGet("/small", ([FromKeyedServices("small")] ICache smallCache) =>
smallCache.Get("date"));

app.Run();

public interface ICache
{
    object Get(string key);
}
public class BigCache : ICache
{
    public object Get(string key) => $"Resolving {key} from big cache.";
}

public class SmallCache : ICache
{
    public object Get(string key) => $"Resolving {key} from small cache.";
}
```

For more information on DI, see Dependency injection in ASP.NET Core.

WebApplicationBuilder

This section contains sample code using WebApplicationBuilder.

Change the content root, application name, and environment

The following code sets the content root, application name, and environment:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    ApplicationName = typeof(Program).Assembly.FullName,
    ContentRootPath = Directory.GetCurrentDirectory(),
    EnvironmentName = Environments.Staging,
    WebRootPath = "customwwwroot"
});

Console.WriteLine($"Application Name:
{builder.Environment.ApplicationName}");
Console.WriteLine($"Environment Name:
{builder.Environment.EnvironmentName}");
Console.WriteLine($"ContentRoot Path:
{builder.Environment.ContentRootPath}");
Console.WriteLine($"WebRootPath: {builder.Environment.WebRootPath}");

var app = builder.Build();
```

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults.

For more information, see ASP.NET Core fundamentals overview

Change the content root, app name, and environment by using environment variables or command line

The following table shows the environment variable and command-line argument used to change the content root, app name, and environment:

Expand table

feature	Environment variable	Command-line argument
Application name	ASPNETCORE_APPLICATIONNAME	--applicationName
Environment name	ASPNETCORE_ENVIRONMENT	--environment
Content root	ASPNETCORE_CONTENTROOT	--contentRoot

Add configuration providers

The following sample adds the INI configuration provider:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Configuration.AddIniFile("appsettings.ini");

var app = builder.Build();
```

For detailed information, see File configuration providers in Configuration in ASP.NET Core.

Read configuration

By default the WebApplicationBuilder reads configuration from multiple sources, including:

- `appSettings.json` and `appSettings.{environment}.json`
- Environment variables
- The command line

For a complete list of configuration sources read, see Default configuration in Configuration in ASP.NET Core.

The following code reads `HelloKey` from configuration and displays the value at the `/` endpoint. If the configuration value is null, "Hello" is assigned to `message`:

C#

```
var builder = WebApplication.CreateBuilder(args);

var message = builder.Configuration["HelloKey"] ?? "Hello";

var app = builder.Build();

app.MapGet("/", () => message);

app.Run();
```

Read the environment

C#

```
var builder = WebApplication.CreateBuilder(args);

if (builder.Environment.IsDevelopment())
{
    Console.WriteLine($"Running in development.");
```

```
}

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Add logging providers

C#

```
var builder = WebApplication.CreateBuilder(args);

// Configure JSON logging to the console.
builder.Logging.AddJsonConsole();

var app = builder.Build();

app.MapGet("/", () => "Hello JSON console!");

app.Run();
```

Add services

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add the memory cache services.
builder.Services.AddMemoryCache();

// Add a custom scoped service.
builder.Services.AddScoped<ITodoRepository, TodoRepository>();
var app = builder.Build();
```

Customize the IHostBuilder

Existing extension methods on IHostBuilder can be accessed using the Host property:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Wait 30 seconds for graceful shutdown.
builder.Host.ConfigureHostOptions(o => o.ShutdownTimeout =
TimeSpan.FromSeconds(30));
```

```
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Customize the IWebHostBuilder

Extension methods on IWebHostBuilder can be accessed using the WebApplicationBuilder.WebHost property.

C#

```
var builder = WebApplication.CreateBuilder(args);

// Change the HTTP server implemenation to be HTTP.sys based
builder.WebHost.UseHttpSys();

var app = builder.Build();

app.MapGet("/", () => "Hello HTTP.sys");

app.Run();
```

Change the web root

By default, the web root is relative to the content root in the `wwwroot` folder. Web root is where the static files middleware looks for static files. Web root can be changed with `WebHostOptions`, the command line, or with the UseWebRoot method:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    // Look for static files in webroot
    WebRootPath = "webroot"
});

var app = builder.Build();

app.Run();
```

Custom dependency injection (DI) container

The following example uses Autofac:

```C#
var builder = WebApplication.CreateBuilder(args);

builder.Host.UseServiceProviderFactory(new AutofacServiceProviderFactory());

// Register services directly with Autofac here. Don't
// call builder.Populate(), that happens in AutofacServiceProviderFactory.
builder.Host.ConfigureContainer<ContainerBuilder>(builder =>
builder.RegisterModule(new MyApplicationModule()));

var app = builder.Build();
```

Add Middleware

Any existing ASP.NET Core middleware can be configured on the `WebApplication`:

```C#
var app = WebApplication.Create(args);

// Setup the file server to serve static files.
app.UseFileServer();

app.MapGet("/", () => "Hello World!");

app.Run();
```

For more information, see ASP.NET Core Middleware

Developer exception page

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults. The developer exception page is enabled in the preconfigured defaults. When the following code is run in the development environment, navigating to `/` renders a friendly page that shows the exception.

```C#
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/", () =>
{
```

```
    throw new InvalidOperationException("Oops, the '/' route has thrown an
exception.");
});

app.Run();
```

ASP.NET Core Middleware

The following table lists some of the middleware frequently used with minimal APIs.

Expand table

Middleware	Description	API
Authentication	Provides authentication support.	UseAuthentication
Authorization	Provides authorization support.	UseAuthorization
CORS	Configures Cross-Origin Resource Sharing.	UseCors
Exception Handler	Globally handles exceptions thrown by the middleware pipeline.	UseExceptionHandler
Forwarded Headers	Forwards proxied headers onto the current request.	UseForwardedHeaders
HTTPS Redirection	Redirects all HTTP requests to HTTPS.	UseHttpsRedirection
HTTP Strict Transport Security (HSTS)	Security enhancement middleware that adds a special response header.	UseHsts
Request Logging	Provides support for logging HTTP requests and responses.	UseHttpLogging
Request Timeouts	Provides support for configuring request timeouts, global default and per endpoint.	`UseRequestTimeouts`
W3C Request Logging	Provides support for logging HTTP requests and responses in the W3C format.	UseW3CLogging
Response Caching	Provides support for caching responses.	UseResponseCaching
Response Compression	Provides support for compressing responses.	UseResponseCompression
Session	Provides support for managing user sessions.	UseSession

Middleware	Description	API
Static Files	Provides support for serving static files and directory browsing.	UseStaticFiles, UseFileServer
WebSockets	Enables the WebSockets protocol.	UseWebSockets

The following sections cover request handling: routing, parameter binding, and responses.

Routing

A configured `WebApplication` supports `Map{Verb}` and MapMethods where `{Verb}` is a camel-cased HTTP method like `Get`, `Post`, `Put` or `Delete`:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "This is a GET");
app.MapPost("/", () => "This is a POST");
app.MapPut("/", () => "This is a PUT");
app.MapDelete("/", () => "This is a DELETE");

app.MapMethods("/options-or-head", new[] { "OPTIONS", "HEAD" },
                           () => "This is an options or head request ");

app.Run();
```

The Delegate arguments passed to these methods are called "route handlers".

Route Handlers

Route handlers are methods that execute when the route matches. Route handlers can be a lambda expression, a local function, an instance method or a static method. Route handlers can be synchronous or asynchronous.

Lambda expression

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();
```

```
app.MapGet("/inline", () => "This is an inline lambda");

var handler = () => "This is a lambda variable";

app.MapGet("/", handler);

app.Run();
```

Local function

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

string LocalFunction() => "This is local function";

app.MapGet("/", LocalFunction);

app.Run();
```

Instance method

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

var handler = new HelloHandler();

app.MapGet("/", handler.Hello);

app.Run();

class HelloHandler
{
    public string Hello()
    {
        return "Hello Instance method";
    }
}
```

Static method

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", HelloHandler.Hello);

app.Run();

class HelloHandler
{
    public static string Hello()
    {
        return "Hello static method";
    }
}
```

Endpoint defined outside of `Program.cs`

Minimal APIs don't have to be located in `Program.cs`.

`Program.cs`

C#

```
using MinAPISeparateFile;

var builder = WebApplication.CreateSlimBuilder(args);

var app = builder.Build();

TodoEndpoints.Map(app);

app.Run();
```

`TodoEndpoints.cs`

C#

```
namespace MinAPISeparateFile;

public static class TodoEndpoints
{
    public static void Map(WebApplication app)
    {
        app.MapGet("/", async context =>
        {
            // Get all todo items
            await context.Response.WriteAsJsonAsync(new { Message = "All
todo items" });
        });
```

```
        app.MapGet("/{id}", async context =>
        {
            // Get one todo item
            await context.Response.WriteAsJsonAsync(new { Message = "One
todo item" });
        });
    }
}
```

See also Route groups later in this article.

Named endpoints and link generation

Endpoints can be given names in order to generate URLs to the endpoint. Using a named endpoint avoids having to hard code paths in an app:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/hello", () => "Hello named route")
   .WithName("hi");

app.MapGet("/", (LinkGenerator linker) =>
        $"The link to the hello route is {linker.GetPathByName("hi", values:
null)}");

app.Run();
```

The preceding code displays `The link to the hello route is /hello` from the `/` endpoint.

NOTE: Endpoint names are case sensitive.

Endpoint names:

- Must be globally unique.
- Are used as the OpenAPI operation id when OpenAPI support is enabled. For more information, see OpenAPI.

Route Parameters

Route parameters can be captured as part of the route pattern definition:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/users/{userId}/books/{bookId}",
    (int userId, int bookId) => $"The user id is {userId} and book id is
{bookId}");

app.Run();
```

The preceding code returns `The user id is 3 and book id is 7` from the URI `/users/3/books/7`.

The route handler can declare the parameters to capture. When a request is made to a route with parameters declared to capture, the parameters are parsed and passed to the handler. This makes it easy to capture the values in a type safe way. In the preceding code, `userId` and `bookId` are both `int`.

In the preceding code, if either route value cannot be converted to an `int`, an exception is thrown. The GET request `/users/hello/books/3` throws the following exception:

```
BadHttpRequestException: Failed to bind parameter "int userId" from "hello".
```

Wildcard and catch all routes

The following catch all route returns `Routing to hello` from the `/posts/hello' endpoint:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/posts/{*rest}", (string rest) => $"Routing to {rest}");

app.Run();
```

Route constraints

Route constraints constrain the matching behavior of a route.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/todos/{id:int}", (int id) => db.Todos.Find(id));
```

```
app.MapGet("/todos/{text}", (string text) => db.Todos.Where(t =>
t.Text.Contains(text));
app.MapGet("/posts/{slug:regex(^[a-z0-9_-]+$)}", (string slug) => $"Post
{slug}");

app.Run();
```

The following table demonstrates the preceding route templates and their behavior:

Expand table

Route Template	Example Matching URI
`/todos/{id:int}`	`/todos/1`
`/todos/{text}`	`/todos/something`
`/posts/{slug:regex(^[a-z0-9_-]+$)}`	`/posts/mypost`

For more information, see Route constraint reference in Routing in ASP.NET Core.

Route groups

The MapGroup extension method helps organize groups of endpoints with a common prefix. It reduces repetitive code and allows for customizing entire groups of endpoints with a single call to methods like RequireAuthorization and WithMetadata which add endpoint metadata.

For example, the following code creates two similar groups of endpoints:

C#

```
app.MapGroup("/public/todos")
    .MapTodosApi()
    .WithTags("Public");

app.MapGroup("/private/todos")
    .MapTodosApi()
    .WithTags("Private")
    .AddEndpointFilterFactory(QueryPrivateTodos)
    .RequireAuthorization();

EndpointFilterDelegate QueryPrivateTodos(EndpointFilterFactoryContext
factoryContext, EndpointFilterDelegate next)
{
    var dbContextIndex = -1;

    foreach (var argument in factoryContext.MethodInfo.GetParameters())
```

```
    {
        if (argument.ParameterType == typeof(TodoDb))
        {
            dbContextIndex = argument.Position;
            break;
        }
    }

    // Skip filter if the method doesn't have a TodoDb parameter.
    if (dbContextIndex < 0)
    {
        return next;
    }

    return async invocationContext =>
    {
        var dbContext = invocationContext.GetArgument<TodoDb>
(dbContextIndex);
        dbContext.IsPrivate = true;

        try
        {
            return await next(invocationContext);
        }
        finally
        {
            // This should only be relevant if you're pooling or otherwise
reusing the DbContext instance.
            dbContext.IsPrivate = false;
        }
    };
}
```

C#

```
public static RouteGroupBuilder MapTodosApi(this RouteGroupBuilder group)
{
    group.MapGet("/", GetAllTodos);
    group.MapGet("/{id}", GetTodo);
    group.MapPost("/", CreateTodo);
    group.MapPut("/{id}", UpdateTodo);
    group.MapDelete("/{id}", DeleteTodo);

    return group;
}
```

In this scenario, you can use a relative address for the `Location` header in the `201 Created` result:

C#

```
public static async Task<Created<Todo>> CreateTodo(Todo todo, TodoDb
database)
{
    await database.AddAsync(todo);
    await database.SaveChangesAsync();

    return TypedResults.Created($"{todo.Id}", todo);
}
```

The first group of endpoints will only match requests prefixed with `/public/todos` and are accessible without any authentication. The second group of endpoints will only match requests prefixed with `/private/todos` and require authentication.

The `QueryPrivateTodos` endpoint filter factory is a local function that modifies the route handler's `TodoDb` parameters to allow to access and store private todo data.

Route groups also support nested groups and complex prefix patterns with route parameters and constraints. In the following example, and route handler mapped to the `user` group can capture the `{org}` and `{group}` route parameters defined in the outer group prefixes.

The prefix can also be empty. This can be useful for adding endpoint metadata or filters to a group of endpoints without changing the route pattern.

C#

```
var all = app.MapGroup("").WithOpenApi();
var org = all.MapGroup("{org}");
var user = org.MapGroup("{user}");
user.MapGet("", (string org, string user) => $"{org}/{user}");
```

Adding filters or metadata to a group behaves the same way as adding them individually to each endpoint before adding any extra filters or metadata that may have been added to an inner group or specific endpoint.

C#

```
var outer = app.MapGroup("/outer");
var inner = outer.MapGroup("/inner");

inner.AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("/inner group filter");
    return next(context);
});

outer.AddEndpointFilter((context, next) =>
```

```
{
    app.Logger.LogInformation("/outer group filter");
    return next(context);
});

inner.MapGet("/", () => "Hi!").AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("MapGet filter");
    return next(context);
});
```

In the above example, the outer filter will log the incoming request before the inner filter even though it was added second. Because the filters were applied to different groups, the order they were added relative to each other does not matter. The order filters are added does matter if applied to the same group or specific endpoint.

A request to `/outer/inner/` will log the following:

.NET CLI

```
/outer group filter
/inner group filter
MapGet filter
```

Parameter binding

Parameter binding is the process of converting request data into strongly typed parameters that are expressed by route handlers. A binding source determines where parameters are bound from. Binding sources can be explicit or inferred based on HTTP method and parameter type.

Supported binding sources:

- Route values
- Query string
- Header
- Body (as JSON)
- Form values
- Services provided by dependency injection
- Custom

The following `GET` route handler uses some of these parameter binding sources:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Added as service
builder.Services.AddSingleton<Service>();

var app = builder.Build();

app.MapGet("/{id}", (int id,
                     int page,
                     [FromHeader(Name = "X-CUSTOM-HEADER")] string
customHeader,
                     Service service) => { });

class Service { }
```

The following table shows the relationship between the parameters used in the preceding example and the associated binding sources.

Expand table

Parameter	Binding Source
`id`	route value
`page`	query string
`customHeader`	header
`service`	Provided by dependency injection

The HTTP methods `GET`, `HEAD`, `OPTIONS`, and `DELETE` don't implicitly bind from body. To bind from body (as JSON) for these HTTP methods, bind explicitly with [FromBody] or read from the HttpRequest.

The following example POST route handler uses a binding source of body (as JSON) for the `person` parameter:

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapPost("/", (Person person) => { });

record Person(string Name, int Age);
```

The parameters in the preceding examples are all bound from request data automatically. To demonstrate the convenience that parameter binding provides, the following route handlers show how to read request data directly from the request:

C#

```
app.MapGet("/{id}", (HttpRequest request) =>
{
    var id = request.RouteValues["id"];
    var page = request.Query["page"];
    var customHeader = request.Headers["X-CUSTOM-HEADER"];

    // ...
});

app.MapPost("/", async (HttpRequest request) =>
{
    var person = await request.ReadFromJsonAsync<Person>();

    // ...
});
```

Explicit Parameter Binding

Attributes can be used to explicitly declare where parameters are bound from.

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

// Added as service
builder.Services.AddSingleton<Service>();

var app = builder.Build();

app.MapGet("/{id}", ([FromRoute] int id,
                     [FromQuery(Name = "p")] int page,
                     [FromServices] Service service,
                     [FromHeader(Name = "Content-Type")] string contentType)
                     => {});

class Service { }

record Person(string Name, int Age);
```

Expand table

Parameter	Binding Source
`id`	route value with the name `id`
`page`	query string with the name `"p"`
`service`	Provided by dependency injection
`contentType`	header with the name `"Content-Type"`

Explicit binding from form values

The [FromForm] attribute binds form values:

C#

```
app.MapPost("/todos", async ([FromForm] string name,
    [FromForm] Visibility visibility, IFormFile? attachment, TodoDb db) =>
{
    var todo = new Todo
    {
        Name = name,
        Visibility = visibility
    };

    if (attachment is not null)
    {
        var attachmentName = Path.GetRandomFileName();

        using var stream = File.Create(Path.Combine("wwwroot",
attachmentName));
        await attachment.CopyToAsync(stream);
    }

    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Ok();
});

// Remaining code removed for brevity.
```

An alternative is to use the [AsParameters] attribute with a custom type that has properties annotated with `[FromForm]`. For example, the following code binds from form values to properties of the `NewTodoRequest` record struct:

C#

```
app.MapPost("/ap/todos", async ([AsParameters] NewTodoRequest request,
TodoDb db) =>
{
    var todo = new Todo
    {
        Name = request.Name,
        Visibility = request.Visibility
    };

    if (request.Attachment is not null)
    {
        var attachmentName = Path.GetRandomFileName();

        using var stream = File.Create(Path.Combine("wwwroot",
attachmentName));
        await request.Attachment.CopyToAsync(stream);

        todo.Attachment = attachmentName;
    }

    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Ok();
});

// Remaining code removed for brevity.
```

C#

```
public record struct NewTodoRequest([FromForm] string Name,
    [FromForm] Visibility Visibility, IFormFile? Attachment);
```

For more information, see the section on AsParameters later in this article.

The complete sample code is in the AspNetCore.Docs.Samples repository.

Secure binding from IFormFile and IFormFileCollection

Complex form binding is supported using IFormFile and IFormFileCollection using the [FromForm]:

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder();
```

```
builder.Services.AddAntiforgery();

var app = builder.Build();
app.UseAntiforgery();

// Generate a form with an anti-forgery token and an /upload endpoint.
app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = MyUtils.GenerateHtmlForm(token.FormFieldName,
token.RequestToken!);
    return Results.Content(html, "text/html");
});

app.MapPost("/upload", async Task<Results<Ok<string>, BadRequest<string>>>
    ([FromForm] FileUploadForm fileUploadForm, HttpContext context,
                                                IAntiforgery antiforgery) =>
{
    await MyUtils.SaveFileWithName(fileUploadForm.FileDocument!,
              fileUploadForm.Name!, app.Environment.ContentRootPath);
    return TypedResults.Ok($"Your file with the description:" +
        $" {fileUploadForm.Description} has been uploaded successfully");
});

app.Run();
```

Parameters bound to the request with `[FromForm]` include an antiforgery token. The antiforgery token is validated when the request is processed. For more information, see Antiforgery with Minimal APIs.

For more information, see Form binding in minimal APIs.

The complete sample code is in the AspNetCore.Docs.Samples repository.

Parameter binding with dependency injection

Parameter binding for minimal APIs binds parameters through dependency injection when the type is configured as a service. It's not necessary to explicitly apply the [FromServices] attribute to a parameter. In the following code, both actions return the time:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddSingleton<IDateTime, SystemDateTime>();

var app = builder.Build();
```

```
app.MapGet("/",   (               IDateTime dateTime) => dateTime.Now);
app.MapGet("/fs", ([FromServices] IDateTime dateTime) => dateTime.Now);
app.Run();
```

Optional parameters

Parameters declared in route handlers are treated as required:

- If a request matches the route, the route handler only runs if all required parameters are provided in the request.
- Failure to provide all required parameters results in an error.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/products", (int pageNumber) => $"Requesting page
{pageNumber}");

app.Run();
```

Expand table

URI	result
`/products?pageNumber=3`	3 returned
`/products`	`BadHttpRequestException`: Required parameter "int pageNumber" wasn't provided from query string.
`/products/1`	HTTP 404 error, no matching route

To make `pageNumber` optional, define the type as optional or provide a default value:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/products", (int? pageNumber) => $"Requesting page {pageNumber
?? 1}");

string ListProducts(int pageNumber = 1) => $"Requesting page {pageNumber}";

app.MapGet("/products2", ListProducts);
```

```
app.Run();
```

Expand table

URI	result
`/products?pageNumber=3`	3 returned
`/products`	1 returned
`/products2`	1 returned

The preceding nullable and default value applies to all sources:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapPost("/products", (Product? product) => { });

app.Run();
```

The preceding code calls the method with a null product if no request body is sent.

NOTE: If invalid data is provided and the parameter is nullable, the route handler is ***not*** run.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/products", (int? pageNumber) => $"Requesting page {pageNumber
?? 1}");

app.Run();
```

Expand table

URI	result
`/products?pageNumber=3`	`3` returned
`/products`	`1` returned

URI	result
`/products?pageNumber=two`	`BadHttpRequestException`: Failed to bind parameter `"Nullable<int> pageNumber"` from "two".
`/products/two`	HTTP 404 error, no matching route

See the Binding Failures section for more information.

Special types

The following types are bound without explicit attributes:

- HttpContext: The context which holds all the information about the current HTTP request or response:

  C#

  ```
  app.MapGet("/", (HttpContext context) =>
  context.Response.WriteAsync("Hello World"));
  ```

- HttpRequest and HttpResponse: The HTTP request and HTTP response:

  C#

  ```
  app.MapGet("/", (HttpRequest request, HttpResponse response) =>
      response.WriteAsync($"Hello World {request.Query["name"]}"));
  ```

- CancellationToken: The cancellation token associated with the current HTTP request:

  C#

  ```
  app.MapGet("/", async (CancellationToken cancellationToken) =>
      await MakeLongRunningRequestAsync(cancellationToken));
  ```

- ClaimsPrincipal: The user associated with the request, bound from HttpContext.User:

  C#

  ```
  app.MapGet("/", (ClaimsPrincipal user) => user.Identity.Name);
  ```

Bind the request body as a `Stream` or `PipeReader`

The request body can bind as a Stream or PipeReader to efficiently support scenarios where the user has to process data and:

- Store the data to blob storage or enqueue the data to a queue provider.
- Process the stored data with a worker process or cloud function.

For example, the data might be enqueued to Azure Queue storage or stored in Azure Blob storage.

The following code implements a background queue:

C#

```
using System.Text.Json;
using System.Threading.Channels;

namespace BackgroundQueueService;

class BackgroundQueue : BackgroundService
{
    private readonly Channel<ReadOnlyMemory<byte>> _queue;
    private readonly ILogger<BackgroundQueue> _logger;

    public BackgroundQueue(Channel<ReadOnlyMemory<byte>> queue,
                           ILogger<BackgroundQueue> logger)
    {
        _queue = queue;
        _logger = logger;
    }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        await foreach (var dataStream in
_queue.Reader.ReadAllAsync(stoppingToken))
        {
            try
            {
                var person = JsonSerializer.Deserialize<Person>
(dataStream.Span)!;
                _logger.LogInformation($"{person.Name} is {person.Age} " +
                                       $"years and from {person.Country}");
            }
            catch (Exception ex)
            {
                _logger.LogError(ex.Message);
            }
        }
    }
}
```

```
class Person
{
    public string Name { get; set; } = String.Empty;
    public int Age { get; set; }
    public string Country { get; set; } = String.Empty;
}
```

The following code binds the request body to a `Stream`:

C#

```
app.MapPost("/register", async (HttpRequest req, Stream body,
                                Channel<ReadOnlyMemory<byte>> queue) =>
{
    if (req.ContentLength is not null && req.ContentLength > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // We're not above the message size and we have a content length, or
    // we're a chunked request and we're going to read up to the
maxMessageSize + 1.
    // We add one to the message size so that we can detect when a chunked
request body
    // is bigger than our configured max.
    var readSize = (int?)req.ContentLength ?? (maxMessageSize + 1);

    var buffer = new byte[readSize];

    // Read at least that many bytes from the body.
    var read = await body.ReadAtLeastAsync(buffer, readSize,
throwOnEndOfStream: false);

    // We read more than the max, so this is a bad request.
    if (read > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // Attempt to send the buffer to the background queue.
    if (queue.Writer.TryWrite(buffer.AsMemory(0..read)))
    {
        return Results.Accepted();
    }

    // We couldn't accept the message since we're overloaded.
    return Results.StatusCode(StatusCodes.Status429TooManyRequests);
});
```

The following code shows the complete `Program.cs` file:

C#

```
using System.Threading.Channels;
using BackgroundQueueService;

var builder = WebApplication.CreateBuilder(args);
// The max memory to use for the upload endpoint on this instance.
var maxMemory = 500 * 1024 * 1024;

// The max size of a single message, staying below the default LOH size of
85K.
var maxMessageSize = 80 * 1024;

// The max size of the queue based on those restrictions
var maxQueueSize = maxMemory / maxMessageSize;

// Create a channel to send data to the background queue.
builder.Services.AddSingleton<Channel<ReadOnlyMemory<byte>>>((_) =>
                    Channel.CreateBounded<ReadOnlyMemory<byte>>
(maxQueueSize));

// Create a background queue service.
builder.Services.AddHostedService<BackgroundQueue>();
var app = builder.Build();

// curl --request POST 'https://localhost:<port>/register' --header
'Content-Type: application/json' --data-raw '{ "Name":"Samson", "Age": 23,
"Country":"Nigeria" }'
// curl --request POST "https://localhost:<port>/register" --header
"Content-Type: application/json" --data-raw "{ \"Name\":\"Samson\", \"Age\":
23, \"Country\":\"Nigeria\" }"
app.MapPost("/register", async (HttpRequest req, Stream body,
                                Channel<ReadOnlyMemory<byte>> queue) =>
{
    if (req.ContentLength is not null && req.ContentLength > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // We're not above the message size and we have a content length, or
    // we're a chunked request and we're going to read up to the
maxMessageSize + 1.
    // We add one to the message size so that we can detect when a chunked
request body
    // is bigger than our configured max.
    var readSize = (int?)req.ContentLength ?? (maxMessageSize + 1);

    var buffer = new byte[readSize];

    // Read at least that many bytes from the body.
    var read = await body.ReadAtLeastAsync(buffer, readSize,
throwOnEndOfStream: false);

    // We read more than the max, so this is a bad request.
```

```
    if (read > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // Attempt to send the buffer to the background queue.
    if (queue.Writer.TryWrite(buffer.AsMemory(0..read)))
    {
        return Results.Accepted();
    }

    // We couldn't accept the message since we're overloaded.
    return Results.StatusCode(StatusCodes.Status429TooManyRequests);
});

app.Run();
```

- When reading data, the `Stream` is the same object as `HttpRequest.Body`.
- The request body isn't buffered by default. After the body is read, it's not rewindable. The stream can't be read multiple times.
- The `Stream` and `PipeReader` aren't usable outside of the minimal action handler as the underlying buffers will be disposed or reused.

File uploads using IFormFile and IFormFileCollection

The following code uses IFormFile and IFormFileCollection to upload file:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.MapPost("/upload", async (IFormFile file) =>
{
    var tempFile = Path.GetTempFileName();
    app.Logger.LogInformation(tempFile);
    using var stream = File.OpenWrite(tempFile);
    await file.CopyToAsync(stream);
});

app.MapPost("/upload_many", async (IFormFileCollection myFiles) =>
{
    foreach (var file in myFiles)
    {
        var tempFile = Path.GetTempFileName();
        app.Logger.LogInformation(tempFile);
        using var stream = File.OpenWrite(tempFile);
        await file.CopyToAsync(stream);
```

```
    }
});

app.Run();
```

Authenticated file upload requests are supported using an Authorization header, a client certificate, or a cookie header.

Binding to forms with IFormCollection, IFormFile, and IFormFileCollection

Binding from form-based parameters using IFormCollection, IFormFile, and IFormFileCollection is supported. OpenAPI metadata is inferred for form parameters to support integration with Swagger UI.

The following code uploads files using inferred binding from the `IFormFile` type:

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();
app.UseAntiforgery();

string GetOrCreateFilePath(string fileName, string filesDirectory =
"uploadFiles")
{
    var directoryPath = Path.Combine(app.Environment.ContentRootPath,
filesDirectory);
    Directory.CreateDirectory(directoryPath);
    return Path.Combine(directoryPath, fileName);
}

async Task UploadFileWithName(IFormFile file, string fileSaveName)
{
    var filePath = GetOrCreateFilePath(fileSaveName);
    await using var fileStream = new FileStream(filePath, FileMode.Create);
    await file.CopyToAsync(fileStream);
}

app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = $"""
      <html>
```

```
        <body>
          <form action="/upload" method="POST" enctype="multipart/form-
data">
            <input name="{token.FormFieldName}" type="hidden" value="
{token.RequestToken}"/>
            <input type="file" name="file" placeholder="Upload an image..."
accept=".jpg,

.jpeg, .png" />
            <input type="submit" />
          </form>
        </body>
      </html>
    """;

    return Results.Content(html, "text/html");
});

app.MapPost("/upload", async Task<Results<Ok<string>,
   BadRequest<string>>> (IFormFile file, HttpContext context, IAntiforgery
antiforgery) =>
{
    var fileSaveName = Guid.NewGuid().ToString("N") +
Path.GetExtension(file.FileName);
    await UploadFileWithName(file, fileSaveName);
    return TypedResults.Ok("File uploaded successfully!");
});

app.Run();
```

Warning: When implementing forms, the app ***must prevent*** Cross-Site Request Forgery (XSRF/CSRF) attacks. In the preceding code, the IAntiforgery service is used to prevent XSRF attacks by generating and validation an antiforgery token:

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();
app.UseAntiforgery();

string GetOrCreateFilePath(string fileName, string filesDirectory =
"uploadFiles")
{
    var directoryPath = Path.Combine(app.Environment.ContentRootPath,
filesDirectory);
    Directory.CreateDirectory(directoryPath);
    return Path.Combine(directoryPath, fileName);
```

```
}

async Task UploadFileWithName(IFormFile file, string fileSaveName)
{
    var filePath = GetOrCreateFilePath(fileSaveName);
    await using var fileStream = new FileStream(filePath, FileMode.Create);
    await file.CopyToAsync(fileStream);
}

app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = $"""
      <html>
        <body>
          <form action="/upload" method="POST" enctype="multipart/form-
data">
            <input name="{token.FormFieldName}" type="hidden" value="
{token.RequestToken}"/>
            <input type="file" name="file" placeholder="Upload an image..."
accept=".jpg,

.jpeg, .png" />
            <input type="submit" />
          </form>
        </body>
      </html>
    """;

    return Results.Content(html, "text/html");
});

app.MapPost("/upload", async Task<Results<Ok<string>,
   BadRequest<string>>> (IFormFile file, HttpContext context, IAntiforgery
antiforgery) =>
{
    var fileSaveName = Guid.NewGuid().ToString("N") +
Path.GetExtension(file.FileName);
    await UploadFileWithName(file, fileSaveName);
    return TypedResults.Ok("File uploaded successfully!");
});

app.Run();
```

For more information on XSRF attacks, see Antiforgery with Minimal APIs

For more information, see Form binding in minimal APIs ↗;

Bind to collections and complex types from forms

Binding is supported for:

- Collections, for example List and Dictionary
- Complex types, for example, `Todo` or `Project`

The following code shows:

- A minimal endpoint that binds a multi-part form input to a complex object.
- How to use the antiforgery services to support the generation and validation of antiforgery tokens.

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAntiforgery();

var app = builder.Build();

app.UseAntiforgery();

app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = $"""
        <html><body>
           <form action="/todo" method="POST" enctype="multipart/form-data">
               <input name="{token.FormFieldName}"
                               type="hidden" value="{token.RequestToken}"
/>
               <input type="text" name="name" />
               <input type="date" name="dueDate" />
               <input type="checkbox" name="isCompleted" value="true" />
               <input type="submit" />
               <input name="isCompleted" type="hidden" value="false" />
           </form>
        </body></html>
    """;
    return Results.Content(html, "text/html");
});

app.MapPost("/todo", async Task<Results<Ok<Todo>, BadRequest<string>>>
               ([FromForm] Todo todo, HttpContext context, IAntiforgery
antiforgery) =>
{
    try
    {
        await antiforgery.ValidateRequestAsync(context);
        return TypedResults.Ok(todo);
    }
    catch (AntiforgeryValidationException e)
```

```
    {
        return TypedResults.BadRequest("Invalid antiforgery token");
    }
});

app.Run();

class Todo
{
    public string Name { get; set; } = string.Empty;
    public bool IsCompleted { get; set; } = false;
    public DateTime DueDate { get; set; } =
DateTime.Now.Add(TimeSpan.FromDays(1));
}
```

In the preceding code:

- The target parameter ***must*** be annotated with the [FromForm] attribute to disambiguate from parameters that should be read from the JSON body.
- Binding from complex or collection types is ***not*** supported for minimal APIs that are compiled with the Request Delegate Generator.
- The markup shows an additional hidden input with a name of `isCompleted` and a value of `false`. If the `isCompleted` checkbox is checked when the form is submitted, both values `true` and `false` are submitted as values. If the checkbox is unchecked, only the hidden input value `false` is submitted. The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

An example of the form data submitted to the preceding endpoint looks as follows:

txt

```
__RequestVerificationToken:
CfDJ8Bveip67DklJm5vI2PF2VOUZ594RC8kcGWpTnVV17zCLZi1yrs-
CSz426ZRRrQnEJ0gybB0AD7hTU-0EGJXDU-OaJaktgAtWLIaaEWMOWCkoxYYm-
9U9eLV7INSUrQ6yBHqdMEE_aJpD4AI72gYiCqc
name: Walk the dog
dueDate: 2024-04-06
isCompleted: true
isCompleted: false
```

Bind arrays and string values from headers and query strings

The following code demonstrates binding query strings to an array of primitive types, string arrays, and StringValues:

C#

```
// Bind query string values to a primitive type array.
// GET  /tags?q=1&q=2&q=3
app.MapGet("/tags", (int[] q) =>
                      $"tag1: {q[0]} , tag2: {q[1]}, tag3: {q[2]}");

// Bind to a string array.
// GET /tags2?names=john&names=jack&names=jane
app.MapGet("/tags2", (string[] names) =>
            $"tag1: {names[0]} , tag2: {names[1]}, tag3: {names[2]}");

// Bind to StringValues.
// GET /tags3?names=john&names=jack&names=jane
app.MapGet("/tags3", (StringValues names) =>
            $"tag1: {names[0]} , tag2: {names[1]}, tag3: {names[2]}");
```

Binding query strings or header values to an array of complex types is supported when the type has `TryParse` implemented. The following code binds to a string array and returns all the items with the specified tags:

C#

```
// GET /todoitems/tags?tags=home&tags=work
app.MapGet("/todoitems/tags", async (Tag[] tags, TodoDb db) =>
{
    return await db.Todos
        .Where(t => tags.Select(i => i.Name).Contains(t.Tag.Name))
        .ToListAsync();
});
```

The following code shows the model and the required `TryParse` implementation:

C#

```
public class Todo
{
    public int Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }

    // This is an owned entity.
    public Tag Tag { get; set; } = new();
}

[Owned]
public class Tag
```

```
{
    public string? Name { get; set; } = "n/a";

    public static bool TryParse(string? name, out Tag tag)
    {
        if (name is null)
        {
            tag = default!;
            return false;
        }

        tag = new Tag { Name = name };
        return true;
    }
}
```

The following code binds to an `int` array:

C#

```
// GET /todoitems/query-string-ids?ids=1&ids=3
app.MapGet("/todoitems/query-string-ids", async (int[] ids, TodoDb db) =>
{
    return await db.Todos
        .Where(t => ids.Contains(t.Id))
        .ToListAsync();
});
```

To test the preceding code, add the following endpoint to populate the database with `Todo` items:

C#

```
// POST /todoitems/batch
app.MapPost("/todoitems/batch", async (Todo[] todos, TodoDb db) =>
{
    await db.Todos.AddRangeAsync(todos);
    await db.SaveChangesAsync();

    return Results.Ok(todos);
});
```

Use a tool like HttpRepl to pass the following data to the previous endpoint:

C#

```
[
    {
        "id": 1,
        "name": "Have Breakfast",
```

```
        "isComplete": true,
        "tag": {
            "name": "home"
        }
    },
    {
        "id": 2,
        "name": "Have Lunch",
        "isComplete": true,
        "tag": {
            "name": "work"
        }
    },
    {
        "id": 3,
        "name": "Have Supper",
        "isComplete": true,
        "tag": {
            "name": "home"
        }
    },
    {
        "id": 4,
        "name": "Have Snacks",
        "isComplete": true,
        "tag": {
            "name": "N/A"
        }
    }
]
```

The following code binds to the header key `X-Todo-Id` and returns the `Todo` items with matching `Id` values:

C#

```
// GET /todoitems/header-ids
// The keys of the headers should all be X-Todo-Id with different values
app.MapGet("/todoitems/header-ids", async ([FromHeader(Name = "X-Todo-Id")]
int[] ids, TodoDb db) =>
{
    return await db.Todos
        .Where(t => ids.Contains(t.Id))
        .ToListAsync();
});
```

ⓘ Note

When binding a `string[]` from a query string, the absence of any matching query string value will result in an empty array instead of a null value.

Parameter binding for argument lists with [AsParameters]

AsParametersAttribute enables simple parameter binding to types and not complex or recursive model binding.

Consider the following code:

C#

```
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
var app = builder.Build();

app.MapGet("/todoitems", async (TodoDb db) =>
    await db.Todos.Select(x => new TodoItemDTO(x)).ToListAsync());

app.MapGet("/todoitems/{id}",
                            async (int Id, TodoDb Db) =>
    await Db.Todos.FindAsync(Id)
        is Todo todo
            ? Results.Ok(new TodoItemDTO(todo))
            : Results.NotFound());
// Remaining code removed for brevity.
```

Consider the following `GET` endpoint:

C#

```
app.MapGet("/todoitems/{id}",
                            async (int Id, TodoDb Db) =>
    await Db.Todos.FindAsync(Id)
        is Todo todo
            ? Results.Ok(new TodoItemDTO(todo))
            : Results.NotFound());
```

The following `struct` can be used to replace the preceding highlighted parameters:

C#

```
struct TodoItemRequest
{
    public int Id { get; set; }
    public TodoDb Db { get; set; }
}
```

The refactored `GET` endpoint uses the preceding `struct` with the AsParameters attribute:

C#

```
app.MapGet("/ap/todoitems/{id}",
                                async ([AsParameters] TodoItemRequest
request) =>
    await request.Db.Todos.FindAsync(request.Id)
        is Todo todo
            ? Results.Ok(new TodoItemDTO(todo))
            : Results.NotFound());
```

The following code shows additional endpoints in the app:

C#

```
app.MapPost("/todoitems", async (TodoItemDTO Dto, TodoDb Db) =>
{
    var todoItem = new Todo
    {
        IsComplete = Dto.IsComplete,
        Name = Dto.Name
    };

    Db.Todos.Add(todoItem);
    await Db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todoItem.Id}", new
TodoItemDTO(todoItem));
});

app.MapPut("/todoitems/{id}", async (int Id, TodoItemDTO Dto, TodoDb Db) =>
{
    var todo = await Db.Todos.FindAsync(Id);

    if (todo is null) return Results.NotFound();

    todo.Name = Dto.Name;
    todo.IsComplete = Dto.IsComplete;

    await Db.SaveChangesAsync();

    return Results.NoContent();
```

```
});

app.MapDelete("/todoitems/{id}", async (int Id, TodoDb Db) =>
{
    if (await Db.Todos.FindAsync(Id) is Todo todo)
    {
        Db.Todos.Remove(todo);
        await Db.SaveChangesAsync();
        return Results.Ok(new TodoItemDTO(todo));
    }

    return Results.NotFound();
});
```

The following classes are used to refactor the parameter lists:

C#

```
class CreateTodoItemRequest
{
    public TodoItemDTO Dto { get; set; } = default!;
    public TodoDb Db { get; set; } = default!;
}

class EditTodoItemRequest
{
    public int Id { get; set; }
    public TodoItemDTO Dto { get; set; } = default!;
    public TodoDb Db { get; set; } = default!;
}
```

The following code shows the refactored endpoints using `AsParameters` and the preceding `struct` and classes:

C#

```
app.MapPost("/ap/todoitems", async ([AsParameters] CreateTodoItemRequest
request) =>
{
    var todoItem = new Todo
    {
        IsComplete = request.Dto.IsComplete,
        Name = request.Dto.Name
    };

    request.Db.Todos.Add(todoItem);
    await request.Db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todoItem.Id}", new
TodoItemDTO(todoItem));
});
```

```
app.MapPut("/ap/todoitems/{id}", async ([AsParameters] EditTodoItemRequest
request) =>
{
    var todo = await request.Db.Todos.FindAsync(request.Id);

    if (todo is null) return Results.NotFound();

    todo.Name = request.Dto.Name;
    todo.IsComplete = request.Dto.IsComplete;

    await request.Db.SaveChangesAsync();

    return Results.NoContent();
});

app.MapDelete("/ap/todoitems/{id}", async ([AsParameters] TodoItemRequest
request) =>
{
    if (await request.Db.Todos.FindAsync(request.Id) is Todo todo)
    {
        request.Db.Todos.Remove(todo);
        await request.Db.SaveChangesAsync();
        return Results.Ok(new TodoItemDTO(todo));
    }

    return Results.NotFound();
});
```

The following record types can be used to replace the preceding parameters:

C#

```
record TodoItemRequest(int Id, TodoDb Db);
record CreateTodoItemRequest(TodoItemDTO Dto, TodoDb Db);
record EditTodoItemRequest(int Id, TodoItemDTO Dto, TodoDb Db);
```

Using a `struct` with `AsParameters` can be more performant than using a `record` type.

The complete sample code in the AspNetCore.Docs.Samples repository.

Custom Binding

There are two ways to customize parameter binding:

1. For route, query, and header binding sources, bind custom types by adding a static `TryParse` method for the type.
2. Control the binding process by implementing a `BindAsync` method on a type.

TryParse

`TryParse` has two APIs:

```C#
public static bool TryParse(string value, out T result);
public static bool TryParse(string value, IFormatProvider provider, out T
result);
```

The following code displays `Point: 12.3, 10.1` with the URI `/map?Point=12.3,10.1`:

```C#
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

// GET /map?Point=12.3,10.1
app.MapGet("/map", (Point point) => $"Point: {point.X}, {point.Y}");

app.Run();

public class Point
{
    public double X { get; set; }
    public double Y { get; set; }

    public static bool TryParse(string? value, IFormatProvider? provider,
                                out Point? point)
    {
        // Format is "(12.3,10.1)"
        var trimmedValue = value?.TrimStart('(').TrimEnd(')');
        var segments = trimmedValue?.Split(',',
                StringSplitOptions.RemoveEmptyEntries |
StringSplitOptions.TrimEntries);
        if (segments?.Length == 2
            && double.TryParse(segments[0], out var x)
            && double.TryParse(segments[1], out var y))
        {
            point = new Point { X = x, Y = y };
            return true;
        }

        point = null;
        return false;
    }
}
```

BindAsync

`BindAsync` has the following APIs:

```
C#

public static ValueTask<T?> BindAsync(HttpContext context, ParameterInfo
parameter);
public static ValueTask<T?> BindAsync(HttpContext context);
```

The following code displays `SortBy:xyz, SortDirection:Desc, CurrentPage:99` with the URI `/products?SortBy=xyz&SortDir=Desc&Page=99`:

```
C#

using System.Reflection;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

// GET /products?SortBy=xyz&SortDir=Desc&Page=99
app.MapGet("/products", (PagingData pageData) => $"SortBy:{pageData.SortBy},
" +
       $"SortDirection:{pageData.SortDirection}, CurrentPage:
{pageData.CurrentPage}");

app.Run();

public class PagingData
{
    public string? SortBy { get; init; }
    public SortDirection SortDirection { get; init; }
    public int CurrentPage { get; init; } = 1;

    public static ValueTask<PagingData?> BindAsync(HttpContext context,
                                                   ParameterInfo parameter)
    {
        const string sortByKey = "sortBy";
        const string sortDirectionKey = "sortDir";
        const string currentPageKey = "page";

        Enum.TryParse<SortDirection>
(context.Request.Query[sortDirectionKey],
                                     ignoreCase: true, out var
sortDirection);
        int.TryParse(context.Request.Query[currentPageKey], out var page);
        page = page == 0 ? 1 : page;

        var result = new PagingData
        {
            SortBy = context.Request.Query[sortByKey],
            SortDirection = sortDirection,
            CurrentPage = page
        };
```

```
        return ValueTask.FromResult<PagingData?>(result);
    }
}

public enum SortDirection
{
    Default,
    Asc,
    Desc
}
```

Binding failures

When binding fails, the framework logs a debug message and returns various status codes to the client depending on the failure mode.

Expand table

Failure mode	Nullable Parameter Type	Binding Source	Status code
`{ParameterType}.TryParse` returns `false`	yes	route/query/header	400
`{ParameterType}.BindAsync` returns `null`	yes	custom	400
`{ParameterType}.BindAsync` throws	doesn't matter	custom	500
Failure to deserialize JSON body	doesn't matter	body	400
Wrong content type (not `application/json`)	doesn't matter	body	415

Binding Precedence

The rules for determining a binding source from a parameter:

1. Explicit attribute defined on parameter (From* attributes) in the following order:
    a. Route values: [FromRoute]
    b. Query string: [FromQuery]
    c. Header: [FromHeader]
    d. Body: [FromBody]
    e. Form: [FromForm]
    f. Service: [FromServices]

g. Parameter values: [AsParameters]

2. Special types
   a. HttpContext
   b. HttpRequest (HttpContext.Request)
   c. HttpResponse (HttpContext.Response)
   d. ClaimsPrincipal (HttpContext.User)
   e. CancellationToken (HttpContext.RequestAborted)
   f. IFormCollection (HttpContext.Request.Form)
   g. IFormFileCollection (HttpContext.Request.Form.Files)
   h. IFormFile (HttpContext.Request.Form.Files[paramName])
   i. Stream (HttpContext.Request.Body)
   j. PipeReader (HttpContext.Request.BodyReader)
3. Parameter type has a valid static BindAsync method.
4. Parameter type is a string or has a valid static TryParse method.
   a. If the parameter name exists in the route template for example, `app.Map("/todo/{id}", (int id) => {});`, then it's bound from the route.
   b. Bound from the query string.
5. If the parameter type is a service provided by dependency injection, it uses that service as the source.
6. The parameter is from the body.

Configure JSON deserialization options for body binding

The body binding source uses System.Text.Json for deserialization. It is ***not*** possible to change this default, but JSON serialization and deserialization options can be configured.

Configure JSON deserialization options globally

Options that apply globally for an app can be configured by invoking ConfigureHttpJsonOptions. The following example includes public fields and formats JSON output.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options => {
    options.SerializerOptions.WriteIndented = true;
    options.SerializerOptions.IncludeFields = true;
});

var app = builder.Build();
```

```
app.MapPost("/", (Todo todo) => {
    if (todo is not null) {
        todo.Name = todo.NameField;
    }
    return todo;
});

app.Run();

class Todo {
    public string? Name { get; set; }
    public string? NameField;
    public bool IsComplete { get; set; }
}
// If the request body contains the following JSON:
//
// {"nameField":"Walk dog", "isComplete":false}
//
// The endpoint returns the following JSON:
//
// {
//    "name":"Walk dog",
//    "nameField":"Walk dog",
//    "isComplete":false
// }
```

Since the sample code configures both serialization and deserialization, it can read `NameField` and include `NameField` in the output JSON.

Configure JSON deserialization options for an endpoint

ReadFromJsonAsync has overloads that accept a JsonSerializerOptions object. The following example includes public fields and formats JSON output.

C#

```
using System.Text.Json;

var app = WebApplication.Create();

var options = new JsonSerializerOptions(JsonSerializerDefaults.Web) {
    IncludeFields = true,
    WriteIndented = true
};

app.MapPost("/", async (HttpContext context) => {
    if (context.Request.HasJsonContentType()) {
        var todo = await context.Request.ReadFromJsonAsync<Todo>(options);
        if (todo is not null) {
            todo.Name = todo.NameField;
```

```
        }
        return Results.Ok(todo);
    }
    else {
        return Results.BadRequest();
    }
});

app.Run();

class Todo
{
    public string? Name { get; set; }
    public string? NameField;
    public bool IsComplete { get; set; }
}
// If the request body contains the following JSON:
//
// {"nameField":"Walk dog", "isComplete":false}
//
// The endpoint returns the following JSON:
//
// {
//    "name":"Walk dog",
//    "isComplete":false
// }
```

Since the preceding code applies the customized options only to deserialization, the output JSON excludes `NameField`.

Read the request body

Read the request body directly using a HttpContext or HttpRequest parameter:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapPost("/uploadstream", async (IConfiguration config, HttpRequest
request) =>
{
    var filePath = Path.Combine(config["StoredFilesPath"],
Path.GetRandomFileName());

    await using var writeStream = File.Create(filePath);
    await request.BodyReader.CopyToAsync(writeStream);
});

app.Run();
```

The preceding code:

- Accesses the request body using HttpRequest.BodyReader.
- Copies the request body to a local file.

Responses

Route handlers support the following types of return values:

1. `IResult` based - This includes `Task<IResult>` and `ValueTask<IResult>`
2. `string` - This includes `Task<string>` and `ValueTask<string>`
3. `T` (Any other type) - This includes `Task<T>` and `ValueTask<T>`

Expand table

Return value	Behavior	Content-Type
`IResult`	The framework calls IResult.ExecuteAsync	Decided by the `IResult` implementation
`string`	The framework writes the string directly to the response	`text/plain`
`T` (Any other type)	The framework JSON-serializes the response	`application/json`

For a more in-depth guide to route handler return values see Create responses in Minimal API applications

Example return values

string return values

C#

```
app.MapGet("/hello", () => "Hello World");
```

JSON return values

C#

```
app.MapGet("/hello", () => new { Message = "Hello World" });
```

Return TypedResults

The following code returns a TypedResults:

```
C#
```

```
app.MapGet("/hello", () => TypedResults.Ok(new Message() {  Text = "Hello
World!" }));
```

Returning `TypedResults` is preferred to returning Results. For more information, see TypedResults vs Results.

IResult return values

```
C#
```

```
app.MapGet("/hello", () => Results.Ok(new { Message = "Hello World" }));
```

The following example uses the built-in result types to customize the response:

```
C#
```

```
app.MapGet("/api/todoitems/{id}", async (int id, TodoDb db) =>
         await db.Todos.FindAsync(id)
         is Todo todo
         ? Results.Ok(todo)
         : Results.NotFound())
   .Produces<Todo>(StatusCodes.Status200OK)
   .Produces(StatusCodes.Status404NotFound);
```

JSON

```
C#
```

```
app.MapGet("/hello", () => Results.Json(new { Message = "Hello World" }));
```

Custom Status Code

```
C#
```

```
app.MapGet("/405", () => Results.StatusCode(405));
```

Text

```
C#

app.MapGet("/text", () => Results.Text("This is some text"));
```

Stream

```
C#

var proxyClient = new HttpClient();
app.MapGet("/pokemon", async () =>
{
    var stream = await
proxyClient.GetStreamAsync("http://contoso/pokedex.json");
    // Proxy the response as JSON
    return Results.Stream(stream, "application/json");
});
```

See Create responses in Minimal API applications for more examples.

Redirect

```
C#

app.MapGet("/old-path", () => Results.Redirect("/new-path"));
```

File

```
C#

app.MapGet("/download", () => Results.File("myfile.text"));
```

Built-in results

Common result helpers exist in the Results and TypedResults static classes. Returning `TypedResults` is preferred to returning `Results`. For more information, see TypedResults vs Results.

Customizing results

Applications can control responses by implementing a custom IResult type. The following code is an example of an HTML result type:

C#

```
using System.Net.Mime;
using System.Text;
static class ResultsExtensions
{
    public static IResult Html(this IResultExtensions resultExtensions,
string html)
    {
        ArgumentNullException.ThrowIfNull(resultExtensions);

        return new HtmlResult(html);
    }
}

class HtmlResult : IResult
{
    private readonly string _html;

    public HtmlResult(string html)
    {
        _html = html;
    }

    public Task ExecuteAsync(HttpContext httpContext)
    {
        httpContext.Response.ContentType = MediaTypeNames.Text.Html;
        httpContext.Response.ContentLength =
Encoding.UTF8.GetByteCount(_html);
        return httpContext.Response.WriteAsync(_html);
    }
}
```

We recommend adding an extension method to Microsoft.AspNetCore.Http.IResultExtensions to make these custom results more discoverable.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/html", () => Results.Extensions.Html(@$"<!doctype html>
<html>
    <head><title>miniHTML</title></head>
    <body>
        <h1>Hello World</h1>
        <p>The time on the server is {DateTime.Now:O}</p>
```

```
    </body>
</html>"));

app.Run();
```

Typed results

The IResult interface can represent values returned from minimal APIs that don't utilize the implicit support for JSON serializing the returned object to the HTTP response. The static Results class is used to create varying `IResult` objects that represent different types of responses. For example, setting the response status code or redirecting to another URL.

The types implementing `IResult` are public, allowing for type assertions when testing. For example:

C#

```
[TestClass()]
public class WeatherApiTests
{
    [TestMethod()]
    public void MapWeatherApiTest()
    {
        var result = WeatherApi.GetAllWeathers();
        Assert.IsInstanceOfType(result, typeof(Ok<WeatherForecast[]>));
    }
}
```

You can look at the return types of the corresponding methods on the static TypedResults class to find the correct public `IResult` type to cast to.

See Create responses in Minimal API applications for more examples.

Filters

For more information, see Filters in Minimal API apps.

Authorization

Routes can be protected using authorization policies. These can be declared via the [Authorize] attribute or by using the RequireAuthorization method:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebRPauth.Data;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddAuthorization(o => o.AddPolicy("AdminsOnly",
                                    b => b.RequireClaim("admin", "true")));

var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();

var app = builder.Build();

app.UseAuthorization();

app.MapGet("/auth", [Authorize] () => "This endpoint requires
authorization.");
app.MapGet("/", () => "This endpoint doesn't require authorization.");
app.MapGet("/Identity/Account/Login", () => "Sign in page at this
endpoint.");

app.Run();
```

The preceding code can be written with RequireAuthorization:

C#

```
app.MapGet("/auth", () => "This endpoint requires authorization")
   .RequireAuthorization();
```

The following sample uses policy-based authorization:

C#

```
using Microsoft.AspNetCore.Authorization;
using Microsoft.AspNetCore.Identity;
using Microsoft.EntityFrameworkCore;
using WebRPauth.Data;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddAuthorization(o => o.AddPolicy("AdminsOnly",
                                    b => b.RequireClaim("admin", "true")));
```

```
var connectionString =
builder.Configuration.GetConnectionString("DefaultConnection");
builder.Services.AddDbContext<ApplicationDbContext>(options =>
    options.UseSqlServer(connectionString));
builder.Services.AddDatabaseDeveloperPageExceptionFilter();

builder.Services.AddDefaultIdentity<IdentityUser>(options =>
options.SignIn.RequireConfirmedAccount = true)
    .AddEntityFrameworkStores<ApplicationDbContext>();

var app = builder.Build();

app.UseAuthorization();

app.MapGet("/admin", [Authorize("AdminsOnly")] () =>
                             "The /admin endpoint is for admins only.");

app.MapGet("/admin2", () => "The /admin2 endpoint is for admins only.")
   .RequireAuthorization("AdminsOnly");

app.MapGet("/", () => "This endpoint doesn't require authorization.");
app.MapGet("/Identity/Account/Login", () => "Sign in page at this
endpoint.");

app.Run();
```

Allow unauthenticated users to access an endpoint

The [AllowAnonymous] allows unauthenticated users to access endpoints:

C#

```
app.MapGet("/login", [AllowAnonymous] () => "This endpoint is for all
roles.");

app.MapGet("/login2", () => "This endpoint also for all roles.")
   .AllowAnonymous();
```

CORS

Routes can be CORS enabled using CORS policies. CORS can be declared via the [EnableCors] attribute or by using the RequireCors method. The following samples enable CORS:

C#

```
const string MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
                      builder =>
                      {
                          builder.WithOrigins("http://example.com",
                                              "http://www.contoso.com");
                      });
});

var app = builder.Build();
app.UseCors();

app.MapGet("/",() => "Hello CORS!");

app.Run();
```

C#

```
using Microsoft.AspNetCore.Cors;

const string MyAllowSpecificOrigins = "_myAllowSpecificOrigins";

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors(options =>
{
    options.AddPolicy(name: MyAllowSpecificOrigins,
                      builder =>
                      {
                          builder.WithOrigins("http://example.com",
                                              "http://www.contoso.com");
                      });
});

var app = builder.Build();
app.UseCors();

app.MapGet("/cors", [EnableCors(MyAllowSpecificOrigins)] () =>
                         "This endpoint allows cross origin requests!");
app.MapGet("/cors2", () => "This endpoint allows cross origin requests!")
                     .RequireCors(MyAllowSpecificOrigins);

app.Run();
```

For more information, see Enable Cross-Origin Requests (CORS) in ASP.NET Core

ValidateScopes and ValidateOnBuild

ValidateScopes and ValidateOnBuild are enabled by default in the Development environment but disabled in other environments.

When `ValidateOnBuild` is `true`, the DI container validates the service configuration at build time. If the service configuration is invalid, the build fails at app startup, rather than at runtime when the service is requested.

When `ValidateScopes` is `true`, the DI container validates that a scoped service isn't resolved from the root scope. Resolving a scoped service from the root scope can result in a memory leak because the service is retained in memory longer than the scope of the request.

`ValidateScopes` and `ValidateOnBuild` are false by default in non-Development modes for performance reasons.

The following code shows `ValidateScopes` is enabled by default in development mode but disabled in release mode:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddScoped<MyScopedService>();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    Console.WriteLine("Development environment");
}
else
{
    Console.WriteLine("Release environment");
}

app.MapGet("/", context =>
{
    // Intentionally getting service provider from app, not from the request
    // This causes an exception from attempting to resolve a scoped service
    // outside of a scope.
    // Throws System.InvalidOperationException:
    // 'Cannot resolve scoped service 'MyScopedService' from root provider.'
    var service = app.Services.GetRequiredService<MyScopedService>();
    return context.Response.WriteAsync("Service resolved");
});

app.Run();
```

```
public class MyScopedService { }
```

The following code shows `ValidateOnBuild` is enabled by default in development mode but disabled in release mode:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddScoped<MyScopedService>();
builder.Services.AddScoped<AnotherService>();

// System.AggregateException: 'Some services are not able to be constructed
(Error
// while validating the service descriptor 'ServiceType: AnotherService
Lifetime:
// Scoped ImplementationType: AnotherService': Unable to resolve service for
type
// 'BrokenService' while attempting to activate 'AnotherService'.)'
var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    Console.WriteLine("Development environment");
}
else
{
    Console.WriteLine("Release environment");
}

app.MapGet("/", context =>
{
    var service =
context.RequestServices.GetRequiredService<MyScopedService>();
    return context.Response.WriteAsync("Service resolved correctly!");
});

app.Run();

public class MyScopedService { }

public class AnotherService
{
    public AnotherService(BrokenService brokenService) { }
}

public class BrokenService { }
```

The following code disables `ValidateScopes` and `ValidateOnBuild` in `Development`:

C#

```
var builder = WebApplication.CreateBuilder(args);

if (builder.Environment.IsDevelopment())
{
    Console.WriteLine("Development environment");
    // Doesn't detect the validation problems because ValidateScopes is
false.
    builder.Host.UseDefaultServiceProvider(options =>
    {
        options.ValidateScopes = false;
        options.ValidateOnBuild = false;
    });
}
```

WebApplication and WebApplicationBuilder in Minimal API apps

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

`WebApplication`

The following code is generated by an ASP.NET Core template:

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

The preceding code can be created via `dotnet new web` on the command line or selecting the Empty Web template in Visual Studio.

The following code creates a WebApplication (`app`) without explicitly creating a WebApplicationBuilder:

```
C#

var app = WebApplication.Create(args);

app.MapGet("/", () => "Hello World!");

app.Run();
```

WebApplication.Create initializes a new instance of the WebApplication class with preconfigured defaults.

Working with ports

When a web app is created with Visual Studio or `dotnet new`, a `Properties/launchSettings.json` file is created that specifies the ports the app responds to. In the port setting samples that follow, running the app from Visual Studio returns an error dialog `Unable to connect to web server 'AppName'`. Visual Studio returns an error because it's expecting the port specified in `Properties/launchSettings.json`, but the app is using the port specified by `app.Run("http://localhost:3000")`. Run the following port changing samples from the command line.

The following sections set the port the app responds to.

C#

```
var app = WebApplication.Create(args);

app.MapGet("/", () => "Hello World!");

app.Run("http://localhost:3000");
```

In the preceding code, the app responds to port `3000`.

Multiple ports

In the following code, the app responds to port `3000` and `4000`.

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("http://localhost:3000");
app.Urls.Add("http://localhost:4000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Set the port from the command line

The following command makes the app respond to port `7777`:

.NET CLI

```
dotnet run --urls="https://localhost:7777"
```

If the Kestrel endpoint is also configured in the `appsettings.json` file, the `appsettings.json` file specified URL is used. For more information, see Kestrel endpoint configuration

Read the port from environment

The following code reads the port from the environment:

C#

```
var app = WebApplication.Create(args);

var port = Environment.GetEnvironmentVariable("PORT") ?? "3000";

app.MapGet("/", () => "Hello World");

app.Run($"http://localhost:{port}");
```

The preferred way to set the port from the environment is to use the `ASPNETCORE_URLS` environment variable, which is shown in the following section.

Set the ports via the ASPNETCORE_URLS environment variable

The `ASPNETCORE_URLS` environment variable is available to set the port:

```
ASPNETCORE_URLS=http://localhost:3000
```

`ASPNETCORE_URLS` supports multiple URLs:

```
ASPNETCORE_URLS=http://localhost:3000;https://localhost:5000
```

Listen on all interfaces

The following samples demonstrate listening on all interfaces

http://*:3000

```
C#

var app = WebApplication.Create(args);

app.Urls.Add("http://*:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

http://+:3000

```
C#

var app = WebApplication.Create(args);

app.Urls.Add("http://+:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

`http://0.0.0.0:3000`

```
C#

var app = WebApplication.Create(args);

app.Urls.Add("http://0.0.0.0:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Listen on all interfaces using ASPNETCORE_URLS

The preceding samples can use `ASPNETCORE_URLS`

```

ASPNETCORE_URLS=http://*:3000;https://+:5000;http://0.0.0.0:5005
```

Listen on all interfaces using ASPNETCORE_HTTPS_PORTS

The preceding samples can use `ASPNETCORE_HTTPS_PORTS` and `ASPNETCORE_HTTP_PORTS`.

```
ASPNETCORE_HTTP_PORTS=3000;5005
ASPNETCORE_HTTPS_PORTS=5000
```

For more information, see Configure endpoints for the ASP.NET Core Kestrel web server

Specify HTTPS with development certificate

C#

```
var app = WebApplication.Create(args);

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

For more information on the development certificate, see Trust the ASP.NET Core HTTPS development certificate on Windows and macOS.

Specify HTTPS using a custom certificate

The following sections show how to specify the custom certificate using the `appsettings.json` file and via configuration.

Specify the custom certificate with `appsettings.json`

JSON

```
{
  "Logging": {
    "LogLevel": {
      "Default": "Information",
      "Microsoft.AspNetCore": "Warning"
    }
  },
  "AllowedHosts": "*",
```

```
  "Kestrel": {
    "Certificates": {
      "Default": {
        "Path": "cert.pem",
        "KeyPath": "key.pem"
      }
    }
  }
}
```

Specify the custom certificate via configuration

C#

```
var builder = WebApplication.CreateBuilder(args);

// Configure the cert and the key
builder.Configuration["Kestrel:Certificates:Default:Path"] = "cert.pem";
builder.Configuration["Kestrel:Certificates:Default:KeyPath"] = "key.pem";

var app = builder.Build();

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Use the certificate APIs

C#

```
using System.Security.Cryptography.X509Certificates;

var builder = WebApplication.CreateBuilder(args);

builder.WebHost.ConfigureKestrel(options =>
{
    options.ConfigureHttpsDefaults(httpsOptions =>
    {
        var certPath = Path.Combine(builder.Environment.ContentRootPath,
"cert.pem");
        var keyPath = Path.Combine(builder.Environment.ContentRootPath,
"key.pem");

        httpsOptions.ServerCertificate =
X509Certificate2.CreateFromPemFile(certPath,
                                           keyPath);
    });
```

```
});

var app = builder.Build();

app.Urls.Add("https://localhost:3000");

app.MapGet("/", () => "Hello World");

app.Run();
```

Read the environment

C#

```
var app = WebApplication.Create(args);

if (!app.Environment.IsDevelopment())
{
    app.UseExceptionHandler("/oops");
}

app.MapGet("/", () => "Hello World");
app.MapGet("/oops", () => "Oops! An error happened.");

app.Run();
```

For more information using the environment, see Use multiple environments in ASP.NET Core

Configuration

The following code reads from the configuration system:

C#

```
var app = WebApplication.Create(args);

var message = app.Configuration["HelloKey"] ?? "Config failed!";

app.MapGet("/", () => message);

app.Run();
```

For more information, see Configuration in ASP.NET Core

Logging

The following code writes a message to the log on application startup:

```
C#
```

```
var app = WebApplication.Create(args);

app.Logger.LogInformation("The app started");

app.MapGet("/", () => "Hello World");

app.Run();
```

For more information, see Logging in .NET Core and ASP.NET Core

Access the Dependency Injection (DI) container

The following code shows how to get services from the DI container during application startup:

```
C#
```

```

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddControllers();
builder.Services.AddScoped<SampleService>();

var app = builder.Build();

app.MapControllers();

using (var scope = app.Services.CreateScope())
{
    var sampleService =
scope.ServiceProvider.GetRequiredService<SampleService>();
    sampleService.DoSomething();
}

app.Run();
```

The following code shows how to access keys from the DI container using the [FromKeyedServices] attribute:

```
C#
```

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddKeyedSingleton<ICache, BigCache>("big");
builder.Services.AddKeyedSingleton<ICache, SmallCache>("small");
```

```
var app = builder.Build();

app.MapGet("/big", ([FromKeyedServices("big")] ICache bigCache) =>
bigCache.Get("date"));

app.MapGet("/small", ([FromKeyedServices("small")] ICache smallCache) =>
smallCache.Get("date"));

app.Run();

public interface ICache
{
    object Get(string key);
}
public class BigCache : ICache
{
    public object Get(string key) => $"Resolving {key} from big cache.";
}

public class SmallCache : ICache
{
    public object Get(string key) => $"Resolving {key} from small cache.";
}
```

For more information on DI, see Dependency injection in ASP.NET Core.

WebApplicationBuilder

This section contains sample code using WebApplicationBuilder.

Change the content root, application name, and environment

The following code sets the content root, application name, and environment:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    ApplicationName = typeof(Program).Assembly.FullName,
    ContentRootPath = Directory.GetCurrentDirectory(),
    EnvironmentName = Environments.Staging,
    WebRootPath = "customwwwroot"
});

Console.WriteLine($"Application Name:
{builder.Environment.ApplicationName}");
```

```
Console.WriteLine($"Environment Name:
{builder.Environment.EnvironmentName}");
Console.WriteLine($"ContentRoot Path:
{builder.Environment.ContentRootPath}");
Console.WriteLine($"WebRootPath: {builder.Environment.WebRootPath}");

var app = builder.Build();
```

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults.

For more information, see ASP.NET Core fundamentals overview

Change the content root, app name, and environment by using environment variables or command line

The following table shows the environment variable and command-line argument used to change the content root, app name, and environment:

Expand table

feature	Environment variable	Command-line argument
Application name	ASPNETCORE_APPLICATIONNAME	--applicationName
Environment name	ASPNETCORE_ENVIRONMENT	--environment
Content root	ASPNETCORE_CONTENTROOT	--contentRoot

Add configuration providers

The following sample adds the INI configuration provider:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Configuration.AddIniFile("appsettings.ini");

var app = builder.Build();
```

For detailed information, see File configuration providers in Configuration in ASP.NET Core.

Read configuration

By default the WebApplicationBuilder reads configuration from multiple sources, including:

- `appSettings.json` and `appSettings.{environment}.json`
- Environment variables
- The command line

For a complete list of configuration sources read, see Default configuration in Configuration in ASP.NET Core.

The following code reads `HelloKey` from configuration and displays the value at the `/` endpoint. If the configuration value is null, "Hello" is assigned to `message`:

C#

```
var builder = WebApplication.CreateBuilder(args);

var message = builder.Configuration["HelloKey"] ?? "Hello";

var app = builder.Build();

app.MapGet("/", () => message);

app.Run();
```

Read the environment

C#

```
var builder = WebApplication.CreateBuilder(args);

if (builder.Environment.IsDevelopment())
{
    Console.WriteLine($"Running in development.");
}

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Add logging providers

C#

```
var builder = WebApplication.CreateBuilder(args);

// Configure JSON logging to the console.
builder.Logging.AddJsonConsole();

var app = builder.Build();

app.MapGet("/", () => "Hello JSON console!");

app.Run();
```

Add services

C#

```
var builder = WebApplication.CreateBuilder(args);

// Add the memory cache services.
builder.Services.AddMemoryCache();

// Add a custom scoped service.
builder.Services.AddScoped<ITodoRepository, TodoRepository>();
var app = builder.Build();
```

Customize the IHostBuilder

Existing extension methods on IHostBuilder can be accessed using the Host property:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Wait 30 seconds for graceful shutdown.
builder.Host.ConfigureHostOptions(o => o.ShutdownTimeout =
TimeSpan.FromSeconds(30));

var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.Run();
```

Customize the IWebHostBuilder

Extension methods on IWebHostBuilder can be accessed using the WebApplicationBuilder.WebHost property.

C#

```
var builder = WebApplication.CreateBuilder(args);

// Change the HTTP server implemenation to be HTTP.sys based
builder.WebHost.UseHttpSys();

var app = builder.Build();

app.MapGet("/", () => "Hello HTTP.sys");

app.Run();
```

Change the web root

By default, the web root is relative to the content root in the `wwwroot` folder. Web root is where the static files middleware looks for static files. Web root can be changed with `WebHostOptions`, the command line, or with the UseWebRoot method:

C#

```
var builder = WebApplication.CreateBuilder(new WebApplicationOptions
{
    Args = args,
    // Look for static files in webroot
    WebRootPath = "webroot"
});

var app = builder.Build();

app.Run();
```

Custom dependency injection (DI) container

The following example uses Autofac:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Host.UseServiceProviderFactory(new AutofacServiceProviderFactory());

// Register services directly with Autofac here. Don't
// call builder.Populate(), that happens in AutofacServiceProviderFactory.
builder.Host.ConfigureContainer<ContainerBuilder>(builder =>
builder.RegisterModule(new MyApplicationModule()));
```

```
var app = builder.Build();
```

Add Middleware

Any existing ASP.NET Core middleware can be configured on the `WebApplication`:

C#

```
var app = WebApplication.Create(args);

// Setup the file server to serve static files.
app.UseFileServer();

app.MapGet("/", () => "Hello World!");

app.Run();
```

For more information, see ASP.NET Core Middleware

Developer exception page

WebApplication.CreateBuilder initializes a new instance of the WebApplicationBuilder class with preconfigured defaults. The developer exception page is enabled in the preconfigured defaults. When the following code is run in the development environment, navigating to `/` renders a friendly page that shows the exception.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/", () =>
{
    throw new InvalidOperationException("Oops, the '/' route has thrown an
exception.");
});

app.Run();
```

Route Handlers in Minimal API apps

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

A configured `WebApplication` supports `Map{Verb}` and MapMethods where `{Verb}` is a Pascal-cased HTTP method like `Get`, `Post`, `Put` or `Delete`:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "This is a GET");
app.MapPost("/", () => "This is a POST");
app.MapPut("/", () => "This is a PUT");
app.MapDelete("/", () => "This is a DELETE");

app.MapMethods("/options-or-head", new[] { "OPTIONS", "HEAD" },
                           () => "This is an options or head request ");

app.Run();
```

The Delegate arguments passed to these methods are called "route handlers".

Route handlers

Route handlers are methods that execute when the route matches. Route handlers can be a lambda expression, a local function, an instance method or a static method. Route handlers can be synchronous or asynchronous.

Lambda expression

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();
```

```
app.MapGet("/inline", () => "This is an inline lambda");

var handler = () => "This is a lambda variable";

app.MapGet("/", handler);

app.Run();
```

Local function

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

string LocalFunction() => "This is local function";

app.MapGet("/", LocalFunction);

app.Run();
```

Instance method

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

var handler = new HelloHandler();

app.MapGet("/", handler.Hello);

app.Run();

class HelloHandler
{
    public string Hello()
    {
        return "Hello Instance method";
    }
}
```

Static method

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", HelloHandler.Hello);

app.Run();

class HelloHandler
{
    public static string Hello()
    {
        return "Hello static method";
    }
}
```

Endpoint defined outside of `Program.cs`

Minimal APIs don't have to be located in `Program.cs`.

`Program.cs`

C#

```
using MinAPISeparateFile;

var builder = WebApplication.CreateSlimBuilder(args);

var app = builder.Build();

TodoEndpoints.Map(app);

app.Run();
```

`TodoEndpoints.cs`

C#

```
namespace MinAPISeparateFile;

public static class TodoEndpoints
{
    public static void Map(WebApplication app)
    {
        app.MapGet("/", async context =>
        {
            // Get all todo items
            await context.Response.WriteAsJsonAsync(new { Message = "All
todo items" });
        });
```

```
        app.MapGet("/{id}", async context =>
        {
            // Get one todo item
            await context.Response.WriteAsJsonAsync(new { Message = "One
todo item" });
        });
    }
}
```

See also Route groups later in this article.

Named endpoints and link generation

Endpoints can be given names in order to generate URLs to the endpoint. Using a named endpoint avoids having to hard code paths in an app:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/hello", () => "Hello named route")
   .WithName("hi");

app.MapGet("/", (LinkGenerator linker) =>
        $"The link to the hello route is {linker.GetPathByName("hi", values:
null)}");

app.Run();
```

The preceding code displays `The link to the hello route is /hello` from the `/` endpoint.

NOTE: Endpoint names are case sensitive.

Endpoint names:

- Must be globally unique.
- Are used as the OpenAPI operation id when OpenAPI support is enabled. For more information, see OpenAPI.

Route Parameters

Route parameters can be captured as part of the route pattern definition:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/users/{userId}/books/{bookId}",
    (int userId, int bookId) => $"The user id is {userId} and book id is
{bookId}");

app.Run();
```

The preceding code returns `The user id is 3 and book id is 7` from the URI `/users/3/books/7`.

The route handler can declare the parameters to capture. When a request is made to a route with parameters declared to capture, the parameters are parsed and passed to the handler. This makes it easy to capture the values in a type safe way. In the preceding code, `userId` and `bookId` are both `int`.

In the preceding code, if either route value cannot be converted to an `int`, an exception is thrown. The GET request `/users/hello/books/3` throws the following exception:

```
BadHttpRequestException: Failed to bind parameter "int userId" from "hello".
```

Wildcard and catch all routes

The following catch all route returns `Routing to hello` from the `/posts/hello' endpoint:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/posts/{*rest}", (string rest) => $"Routing to {rest}");

app.Run();
```

Route constraints

Route constraints constrain the matching behavior of a route.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/todos/{id:int}", (int id) => db.Todos.Find(id));
```

```
app.MapGet("/todos/{text}", (string text) => db.Todos.Where(t =>
t.Text.Contains(text));
app.MapGet("/posts/{slug:regex(^[a-z0-9_-]+$)}", (string slug) => $"Post
{slug}");

app.Run();
```

The following table demonstrates the preceding route templates and their behavior:

Expand table

Route Template	Example Matching URI
`/todos/{id:int}`	`/todos/1`
`/todos/{text}`	`/todos/something`
`/posts/{slug:regex(^[a-z0-9_-]+$)}`	`/posts/mypost`

For more information, see Route constraint reference in Routing in ASP.NET Core.

Route groups

The MapGroup extension method helps organize groups of endpoints with a common prefix. It reduces repetitive code and allows for customizing entire groups of endpoints with a single call to methods like RequireAuthorization and WithMetadata which add endpoint metadata.

For example, the following code creates two similar groups of endpoints:

C#

```
app.MapGroup("/public/todos")
    .MapTodosApi()
    .WithTags("Public");

app.MapGroup("/private/todos")
    .MapTodosApi()
    .WithTags("Private")
    .AddEndpointFilterFactory(QueryPrivateTodos)
    .RequireAuthorization();

EndpointFilterDelegate QueryPrivateTodos(EndpointFilterFactoryContext
factoryContext, EndpointFilterDelegate next)
{
    var dbContextIndex = -1;

    foreach (var argument in factoryContext.MethodInfo.GetParameters())
```

```
    {
        if (argument.ParameterType == typeof(TodoDb))
        {
            dbContextIndex = argument.Position;
            break;
        }
    }

    // Skip filter if the method doesn't have a TodoDb parameter.
    if (dbContextIndex < 0)
    {
        return next;
    }

    return async invocationContext =>
    {
        var dbContext = invocationContext.GetArgument<TodoDb>
(dbContextIndex);
        dbContext.IsPrivate = true;

        try
        {
            return await next(invocationContext);
        }
        finally
        {
            // This should only be relevant if you're pooling or otherwise
reusing the DbContext instance.
            dbContext.IsPrivate = false;
        }
    };
}
```

C#

```
public static RouteGroupBuilder MapTodosApi(this RouteGroupBuilder group)
{
    group.MapGet("/", GetAllTodos);
    group.MapGet("/{id}", GetTodo);
    group.MapPost("/", CreateTodo);
    group.MapPut("/{id}", UpdateTodo);
    group.MapDelete("/{id}", DeleteTodo);

    return group;
}
```

In this scenario, you can use a relative address for the `Location` header in the `201 Created` result:

C#

```
public static async Task<Created<Todo>> CreateTodo(Todo todo, TodoDb
database)
{
    await database.AddAsync(todo);
    await database.SaveChangesAsync();

    return TypedResults.Created($"{todo.Id}", todo);
}
```

The first group of endpoints will only match requests prefixed with `/public/todos` and are accessible without any authentication. The second group of endpoints will only match requests prefixed with `/private/todos` and require authentication.

The `QueryPrivateTodos` endpoint filter factory is a local function that modifies the route handler's `TodoDb` parameters to allow to access and store private todo data.

Route groups also support nested groups and complex prefix patterns with route parameters and constraints. In the following example, and route handler mapped to the `user` group can capture the `{org}` and `{group}` route parameters defined in the outer group prefixes.

The prefix can also be empty. This can be useful for adding endpoint metadata or filters to a group of endpoints without changing the route pattern.

C#

```
var all = app.MapGroup("").WithOpenApi();
var org = all.MapGroup("{org}");
var user = org.MapGroup("{user}");
user.MapGet("", (string org, string user) => $"{org}/{user}");
```

Adding filters or metadata to a group behaves the same way as adding them individually to each endpoint before adding any extra filters or metadata that may have been added to an inner group or specific endpoint.

C#

```
var outer = app.MapGroup("/outer");
var inner = outer.MapGroup("/inner");

inner.AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("/inner group filter");
    return next(context);
});

outer.AddEndpointFilter((context, next) =>
```

```
{
    app.Logger.LogInformation("/outer group filter");
    return next(context);
});

inner.MapGet("/", () => "Hi!").AddEndpointFilter((context, next) =>
{
    app.Logger.LogInformation("MapGet filter");
    return next(context);
});
```

In the above example, the outer filter will log the incoming request before the inner filter even though it was added second. Because the filters were applied to different groups, the order they were added relative to each other does not matter. The order filters are added does matter if applied to the same group or specific endpoint.

A request to `/outer/inner/` will log the following:

.NET CLI

```
/outer group filter
/inner group filter
MapGet filter
```

Parameter binding

Parameter binding in Minimal API applications describes the rules in detail for how route handler parameters are populated.

Responses

Create responses in Minimal API applications describes in detail how values returned from route handlers are converted into responses.

Parameter Binding in Minimal API apps

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Parameter binding is the process of converting request data into strongly typed parameters that are expressed by route handlers. A binding source determines where parameters are bound from. Binding sources can be explicit or inferred based on HTTP method and parameter type.

Supported binding sources:

- Route values
- Query string
- Header
- Body (as JSON)
- Form values
- Services provided by dependency injection
- Custom

The following `GET` route handler uses some of these parameter binding sources:

C#

```
var builder = WebApplication.CreateBuilder(args);

// Added as service
builder.Services.AddSingleton<Service>();

var app = builder.Build();

app.MapGet("/{id}", (int id,
                     int page,
                     [FromHeader(Name = "X-CUSTOM-HEADER")] string
customHeader,
                     Service service) => { });

class Service { }
```

The following table shows the relationship between the parameters used in the preceding example and the associated binding sources.

Expand table

Parameter	Binding Source
`id`	route value
`page`	query string
`customHeader`	header
`service`	Provided by dependency injection

The HTTP methods `GET`, `HEAD`, `OPTIONS`, and `DELETE` don't implicitly bind from body. To bind from body (as JSON) for these HTTP methods, bind explicitly with [FromBody] or read from the HttpRequest.

The following example POST route handler uses a binding source of body (as JSON) for the `person` parameter:

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapPost("/", (Person person) => { });

record Person(string Name, int Age);
```

The parameters in the preceding examples are all bound from request data automatically. To demonstrate the convenience that parameter binding provides, the following route handlers show how to read request data directly from the request:

C#

```
app.MapGet("/{id}", (HttpRequest request) =>
{
    var id = request.RouteValues["id"];
    var page = request.Query["page"];
    var customHeader = request.Headers["X-CUSTOM-HEADER"];

    // ...
});

app.MapPost("/", async (HttpRequest request) =>
```

```
{
    var person = await request.ReadFromJsonAsync<Person>();

    // ...
});
```

Explicit Parameter Binding

Attributes can be used to explicitly declare where parameters are bound from.

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

// Added as service
builder.Services.AddSingleton<Service>();

var app = builder.Build();

app.MapGet("/{id}", ([FromRoute] int id,
                     [FromQuery(Name = "p")] int page,
                     [FromServices] Service service,
                     [FromHeader(Name = "Content-Type")] string contentType)
                     => {});

class Service { }

record Person(string Name, int Age);
```

Expand table

Parameter	Binding Source
`id`	route value with the name `id`
`page`	query string with the name `"p"`
`service`	Provided by dependency injection
`contentType`	header with the name `"Content-Type"`

Explicit binding from form values

The [FromForm] attribute binds form values:

C#

```
app.MapPost("/todos", async ([FromForm] string name,
    [FromForm] Visibility visibility, IFormFile? attachment, TodoDb db) =>
{
    var todo = new Todo
    {
        Name = name,
        Visibility = visibility
    };

    if (attachment is not null)
    {
        var attachmentName = Path.GetRandomFileName();

        using var stream = File.Create(Path.Combine("wwwroot",
attachmentName));
        await attachment.CopyToAsync(stream);
    }

    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Ok();
});

// Remaining code removed for brevity.
```

An alternative is to use the [AsParameters] attribute with a custom type that has properties annotated with `[FromForm]`. For example, the following code binds from form values to properties of the `NewTodoRequest` record struct:

C#

```
app.MapPost("/ap/todos", async ([AsParameters] NewTodoRequest request,
TodoDb db) =>
{
    var todo = new Todo
    {
        Name = request.Name,
        Visibility = request.Visibility
    };

    if (request.Attachment is not null)
    {
        var attachmentName = Path.GetRandomFileName();

        using var stream = File.Create(Path.Combine("wwwroot",
attachmentName));
        await request.Attachment.CopyToAsync(stream);

        todo.Attachment = attachmentName;
```

```
    }

    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Ok();
});

// Remaining code removed for brevity.
```

C#

```
public record struct NewTodoRequest([FromForm] string Name,
    [FromForm] Visibility Visibility, IFormFile? Attachment);
```

For more information, see the section on AsParameters later in this article.

The complete sample code is in the AspNetCore.Docs.Samples repository.

Secure binding from IFormFile and IFormFileCollection

Complex form binding is supported using IFormFile and IFormFileCollection using the [FromForm]:

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();
app.UseAntiforgery();

// Generate a form with an anti-forgery token and an /upload endpoint.
app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = MyUtils.GenerateHtmlForm(token.FormFieldName,
token.RequestToken!);
    return Results.Content(html, "text/html");
});
```

```
app.MapPost("/upload", async Task<Results<Ok<string>, BadRequest<string>>>
    ([FromForm] FileUploadForm fileUploadForm, HttpContext context,
                                                IAntiforgery antiforgery) =>
{
    await MyUtils.SaveFileWithName(fileUploadForm.FileDocument!,
              fileUploadForm.Name!, app.Environment.ContentRootPath);
    return TypedResults.Ok($"Your file with the description:" +
        $" {fileUploadForm.Description} has been uploaded successfully");
});

app.Run();
```

Parameters bound to the request with `[FromForm]` include an anti-forgery token. The anti-forgery token is validated when the request is processed. For more information, see Antiforgery with Minimal APIs.

For more information, see Form binding in minimal APIs.

The complete sample code is in the AspNetCore.Docs.Samples repository.

Parameter binding with dependency injection

Parameter binding for minimal APIs binds parameters through dependency injection when the type is configured as a service. It's not necessary to explicitly apply the [FromServices] attribute to a parameter. In the following code, both actions return the time:

C#

```
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddSingleton<IDateTime, SystemDateTime>();

var app = builder.Build();

app.MapGet("/",   (               IDateTime dateTime) => dateTime.Now);
app.MapGet("/fs", ([FromServices] IDateTime dateTime) => dateTime.Now);
app.Run();
```

Optional parameters

Parameters declared in route handlers are treated as required:

- If a request matches the route, the route handler only runs if all required parameters are provided in the request.

- Failure to provide all required parameters results in an error.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/products", (int pageNumber) => $"Requesting page
{pageNumber}");

app.Run();
```

Expand table

URI	result
`/products?pageNumber=3`	3 returned
`/products`	`BadHttpRequestException`: Required parameter "int pageNumber" wasn't provided from query string.
`/products/1`	HTTP 404 error, no matching route

To make `pageNumber` optional, define the type as optional or provide a default value:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/products", (int? pageNumber) => $"Requesting page {pageNumber
?? 1}");

string ListProducts(int pageNumber = 1) => $"Requesting page {pageNumber}";

app.MapGet("/products2", ListProducts);

app.Run();
```

Expand table

URI	result
`/products?pageNumber=3`	3 returned
`/products`	1 returned

URI	result
`/products2`	1 returned

The preceding nullable and default value applies to all sources:

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapPost("/products", (Product? product) => { });

app.Run();
```

The preceding code calls the method with a null product if no request body is sent.

NOTE: If invalid data is provided and the parameter is nullable, the route handler is ***not*** run.

```
C#

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/products", (int? pageNumber) => $"Requesting page {pageNumber
?? 1}");

app.Run();
```

Expand table

URI	result
`/products?pageNumber=3`	`3` returned
`/products`	`1` returned
`/products?pageNumber=two`	`BadHttpRequestException`: Failed to bind parameter `"Nullable<int> pageNumber"` from "two".
`/products/two`	HTTP 404 error, no matching route

See the Binding Failures section for more information.

Special types

The following types are bound without explicit attributes:

- HttpContext: The context which holds all the information about the current HTTP request or response:

  C#

  ```
  app.MapGet("/", (HttpContext context) =>
  context.Response.WriteAsync("Hello World"));
  ```

- HttpRequest and HttpResponse: The HTTP request and HTTP response:

  C#

  ```
  app.MapGet("/", (HttpRequest request, HttpResponse response) =>
      response.WriteAsync($"Hello World {request.Query["name"]}"));
  ```

- CancellationToken: The cancellation token associated with the current HTTP request:

  C#

  ```
  app.MapGet("/", async (CancellationToken cancellationToken) =>
      await MakeLongRunningRequestAsync(cancellationToken));
  ```

- ClaimsPrincipal: The user associated with the request, bound from HttpContext.User:

  C#

  ```
  app.MapGet("/", (ClaimsPrincipal user) => user.Identity.Name);
  ```

Bind the request body as a `Stream` or `PipeReader`

The request body can bind as a Stream or PipeReader to efficiently support scenarios where the user has to process data and:

- Store the data to blob storage or enqueue the data to a queue provider.
- Process the stored data with a worker process or cloud function.

For example, the data might be enqueued to Azure Queue storage or stored in Azure Blob storage.

The following code implements a background queue:

C#

```
using System.Text.Json;
using System.Threading.Channels;

namespace BackgroundQueueService;

class BackgroundQueue : BackgroundService
{
    private readonly Channel<ReadOnlyMemory<byte>> _queue;
    private readonly ILogger<BackgroundQueue> _logger;

    public BackgroundQueue(Channel<ReadOnlyMemory<byte>> queue,
                           ILogger<BackgroundQueue> logger)
    {
        _queue = queue;
        _logger = logger;
    }

    protected override async Task ExecuteAsync(CancellationToken
stoppingToken)
    {
        await foreach (var dataStream in
_queue.Reader.ReadAllAsync(stoppingToken))
        {
            try
            {
                var person = JsonSerializer.Deserialize<Person>
(dataStream.Span)!;
                _logger.LogInformation($"{person.Name} is {person.Age} " +
                                       $"years and from {person.Country}");
            }
            catch (Exception ex)
            {
                _logger.LogError(ex.Message);
            }
        }
    }
}

class Person
{
    public string Name { get; set; } = String.Empty;
    public int Age { get; set; }
    public string Country { get; set; } = String.Empty;
}
```

The following code binds the request body to a `Stream`:

C#

```
app.MapPost("/register", async (HttpRequest req, Stream body,
                                Channel<ReadOnlyMemory<byte>> queue) =>
```

```
{
    if (req.ContentLength is not null && req.ContentLength > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // We're not above the message size and we have a content length, or
    // we're a chunked request and we're going to read up to the
maxMessageSize + 1.
    // We add one to the message size so that we can detect when a chunked
request body
    // is bigger than our configured max.
    var readSize = (int?)req.ContentLength ?? (maxMessageSize + 1);

    var buffer = new byte[readSize];

    // Read at least that many bytes from the body.
    var read = await body.ReadAtLeastAsync(buffer, readSize,
throwOnEndOfStream: false);

    // We read more than the max, so this is a bad request.
    if (read > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // Attempt to send the buffer to the background queue.
    if (queue.Writer.TryWrite(buffer.AsMemory(0..read)))
    {
        return Results.Accepted();
    }

    // We couldn't accept the message since we're overloaded.
    return Results.StatusCode(StatusCodes.Status429TooManyRequests);
});
```

The following code shows the complete `Program.cs` file:

C#

```
using System.Threading.Channels;
using BackgroundQueueService;

var builder = WebApplication.CreateBuilder(args);
// The max memory to use for the upload endpoint on this instance.
var maxMemory = 500 * 1024 * 1024;

// The max size of a single message, staying below the default LOH size of
85K.
var maxMessageSize = 80 * 1024;

// The max size of the queue based on those restrictions
var maxQueueSize = maxMemory / maxMessageSize;
```

```
// Create a channel to send data to the background queue.
builder.Services.AddSingleton<Channel<ReadOnlyMemory<byte>>>((_) =>
                    Channel.CreateBounded<ReadOnlyMemory<byte>>
(maxQueueSize));

// Create a background queue service.
builder.Services.AddHostedService<BackgroundQueue>();
var app = builder.Build();

// curl --request POST 'https://localhost:<port>/register' --header
'Content-Type: application/json' --data-raw '{ "Name":"Samson", "Age": 23,
"Country":"Nigeria" }'
// curl --request POST "https://localhost:<port>/register" --header
"Content-Type: application/json" --data-raw "{ \"Name\":\"Samson\", \"Age\":
23, \"Country\":\"Nigeria\" }"
app.MapPost("/register", async (HttpRequest req, Stream body,
                                Channel<ReadOnlyMemory<byte>> queue) =>
{
    if (req.ContentLength is not null && req.ContentLength > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // We're not above the message size and we have a content length, or
    // we're a chunked request and we're going to read up to the
maxMessageSize + 1.
    // We add one to the message size so that we can detect when a chunked
request body
    // is bigger than our configured max.
    var readSize = (int?)req.ContentLength ?? (maxMessageSize + 1);

    var buffer = new byte[readSize];

    // Read at least that many bytes from the body.
    var read = await body.ReadAtLeastAsync(buffer, readSize,
throwOnEndOfStream: false);

    // We read more than the max, so this is a bad request.
    if (read > maxMessageSize)
    {
        return Results.BadRequest();
    }

    // Attempt to send the buffer to the background queue.
    if (queue.Writer.TryWrite(buffer.AsMemory(0..read)))
    {
        return Results.Accepted();
    }

    // We couldn't accept the message since we're overloaded.
    return Results.StatusCode(StatusCodes.Status429TooManyRequests);
});

app.Run();
```

- When reading data, the `Stream` is the same object as `HttpRequest.Body`.
- The request body isn't buffered by default. After the body is read, it's not rewindable. The stream can't be read multiple times.
- The `Stream` and `PipeReader` aren't usable outside of the minimal action handler as the underlying buffers will be disposed or reused.

File uploads using IFormFile and IFormFileCollection

The following code uses IFormFile and IFormFileCollection to upload file:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/", () => "Hello World!");

app.MapPost("/upload", async (IFormFile file) =>
{
    var tempFile = Path.GetTempFileName();
    app.Logger.LogInformation(tempFile);
    using var stream = File.OpenWrite(tempFile);
    await file.CopyToAsync(stream);
});

app.MapPost("/upload_many", async (IFormFileCollection myFiles) =>
{
    foreach (var file in myFiles)
    {
        var tempFile = Path.GetTempFileName();
        app.Logger.LogInformation(tempFile);
        using var stream = File.OpenWrite(tempFile);
        await file.CopyToAsync(stream);
    }
});

app.Run();
```

Authenticated file upload requests are supported using an Authorization header, a client certificate, or a cookie header.

Binding to forms with IFormCollection, IFormFile, and IFormFileCollection

Binding from form-based parameters using IFormCollection, IFormFile, and IFormFileCollection is supported. OpenAPI metadata is inferred for form parameters to support integration with Swagger UI.

The following code uploads files using inferred binding from the `IFormFile` type:

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();
app.UseAntiforgery();

string GetOrCreateFilePath(string fileName, string filesDirectory =
"uploadFiles")
{
    var directoryPath = Path.Combine(app.Environment.ContentRootPath,
filesDirectory);
    Directory.CreateDirectory(directoryPath);
    return Path.Combine(directoryPath, fileName);
}

async Task UploadFileWithName(IFormFile file, string fileSaveName)
{
    var filePath = GetOrCreateFilePath(fileSaveName);
    await using var fileStream = new FileStream(filePath, FileMode.Create);
    await file.CopyToAsync(fileStream);
}

app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = $"""
      <html>
        <body>
          <form action="/upload" method="POST" enctype="multipart/form-
data">
            <input name="{token.FormFieldName}" type="hidden" value="
{token.RequestToken}"/>
            <input type="file" name="file" placeholder="Upload an image..."
accept=".jpg,

.jpeg, .png" />
            <input type="submit" />
          </form>
        </body>
      </html>
    """;
```

```
    return Results.Content(html, "text/html");
});

app.MapPost("/upload", async Task<Results<Ok<string>,
   BadRequest<string>>> (IFormFile file, HttpContext context, IAntiforgery
antiforgery) =>
{
    var fileSaveName = Guid.NewGuid().ToString("N") +
Path.GetExtension(file.FileName);
    await UploadFileWithName(file, fileSaveName);
    return TypedResults.Ok("File uploaded successfully!");
});

app.Run();
```

Warning: When implementing forms, the app ***must prevent*** Cross-Site Request Forgery (XSRF/CSRF) attacks. In the preceding code, the IAntiforgery service is used to prevent XSRF attacks by generating and validation an anti-forgery token:

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAntiforgery();

var app = builder.Build();
app.UseAntiforgery();

string GetOrCreateFilePath(string fileName, string filesDirectory =
"uploadFiles")
{
    var directoryPath = Path.Combine(app.Environment.ContentRootPath,
filesDirectory);
    Directory.CreateDirectory(directoryPath);
    return Path.Combine(directoryPath, fileName);
}

async Task UploadFileWithName(IFormFile file, string fileSaveName)
{
    var filePath = GetOrCreateFilePath(fileSaveName);
    await using var fileStream = new FileStream(filePath, FileMode.Create);
    await file.CopyToAsync(fileStream);
}

app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = $"""
      <html>
```

```
        <body>
          <form action="/upload" method="POST" enctype="multipart/form-
data">
            <input name="{token.FormFieldName}" type="hidden" value="
{token.RequestToken}"/>
            <input type="file" name="file" placeholder="Upload an image..."
accept=".jpg,

.jpeg, .png" />
            <input type="submit" />
          </form>
        </body>
      </html>
    """;

    return Results.Content(html, "text/html");
});

app.MapPost("/upload", async Task<Results<Ok<string>,
   BadRequest<string>>> (IFormFile file, HttpContext context, IAntiforgery
antiforgery) =>
{
    var fileSaveName = Guid.NewGuid().ToString("N") +
Path.GetExtension(file.FileName);
    await UploadFileWithName(file, fileSaveName);
    return TypedResults.Ok("File uploaded successfully!");
});

app.Run();
```

For more information on XSRF attacks, see Antiforgery with Minimal APIs

For more information, see Form binding in minimal APIs ↗;

Bind to collections and complex types from forms

Binding is supported for:

- Collections, for example List and Dictionary
- Complex types, for example, `Todo` or `Project`

The following code shows:

- A minimal endpoint that binds a multi-part form input to a complex object.
- How to use the anti-forgery services to support the generation and validation of anti-forgery tokens.

C#

```
using Microsoft.AspNetCore.Antiforgery;
using Microsoft.AspNetCore.Http.HttpResults;
using Microsoft.AspNetCore.Mvc;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAntiforgery();

var app = builder.Build();

app.UseAntiforgery();

app.MapGet("/", (HttpContext context, IAntiforgery antiforgery) =>
{
    var token = antiforgery.GetAndStoreTokens(context);
    var html = $"""
        <html><body>
           <form action="/todo" method="POST" enctype="multipart/form-data">
               <input name="{token.FormFieldName}"
                                type="hidden" value="{token.RequestToken}"
/>
               <input type="text" name="name" />
               <input type="date" name="dueDate" />
               <input type="checkbox" name="isCompleted" value="true" />
               <input type="submit" />
               <input name="isCompleted" type="hidden" value="false" />
           </form>
        </body></html>
    """;
    return Results.Content(html, "text/html");
});

app.MapPost("/todo", async Task<Results<Ok<Todo>, BadRequest<string>>>
               ([FromForm] Todo todo, HttpContext context, IAntiforgery
antiforgery) =>
{
    try
    {
        await antiforgery.ValidateRequestAsync(context);
        return TypedResults.Ok(todo);
    }
    catch (AntiforgeryValidationException e)
    {
        return TypedResults.BadRequest("Invalid anti-forgery token");
    }
});

app.Run();

class Todo
{
    public string Name { get; set; } = string.Empty;
    public bool IsCompleted { get; set; } = false;
    public DateTime DueDate { get; set; } =
```

```
DateTime.Now.Add(TimeSpan.FromDays(1));
}
```

In the preceding code:

- The target parameter ***must*** be annotated with the [FromForm] attribute to disambiguate from parameters that should be read from the JSON body.
- Binding from complex or collection types is ***not*** supported for minimal APIs that are compiled with the Request Delegate Generator.
- The markup shows an additional hidden input with a name of `isCompleted` and a value of `false`. If the `isCompleted` checkbox is checked when the form is submitted, both values `true` and `false` are submitted as values. If the checkbox is unchecked, only the hidden input value `false` is submitted. The ASP.NET Core model-binding process reads only the first value when binding to a `bool` value, which results in `true` for checked checkboxes and `false` for unchecked checkboxes.

An example of the form data submitted to the preceding endpoint looks as follows:

txt

```
__RequestVerificationToken:
CfDJ8Bveip67DklJm5vI2PF2VOUZ594RC8kcGWpTnVV17zCLZi1yrs-
CSz426ZRRrQnEJ0gybB0AD7hTU-0EGJXDU-OaJaktgAtWLIaaEWMOWCkoxYYm-
9U9eLV7INSUrQ6yBHqdMEE_aJpD4AI72gYiCqc
name: Walk the dog
dueDate: 2024-04-06
isCompleted: true
isCompleted: false
```

Bind arrays and string values from headers and query strings

The following code demonstrates binding query strings to an array of primitive types, string arrays, and StringValues:

C#

```
// Bind query string values to a primitive type array.
// GET  /tags?q=1&q=2&q=3
app.MapGet("/tags", (int[] q) =>
                      $"tag1: {q[0]} , tag2: {q[1]}, tag3: {q[2]}");

// Bind to a string array.
// GET /tags2?names=john&names=jack&names=jane
```

```
app.MapGet("/tags2", (string[] names) =>
            $"tag1: {names[0]} , tag2: {names[1]}, tag3: {names[2]}");

// Bind to StringValues.
// GET /tags3?names=john&names=jack&names=jane
app.MapGet("/tags3", (StringValues names) =>
            $"tag1: {names[0]} , tag2: {names[1]}, tag3: {names[2]}");
```

Binding query strings or header values to an array of complex types is supported when the type has `TryParse` implemented. The following code binds to a string array and returns all the items with the specified tags:

C#

```
// GET /todoitems/tags?tags=home&tags=work
app.MapGet("/todoitems/tags", async (Tag[] tags, TodoDb db) =>
{
    return await db.Todos
        .Where(t => tags.Select(i => i.Name).Contains(t.Tag.Name))
        .ToListAsync();
});
```

The following code shows the model and the required `TryParse` implementation:

C#

```
public class Todo
{
    public int Id { get; set; }
    public string? Name { get; set; }
    public bool IsComplete { get; set; }

    // This is an owned entity.
    public Tag Tag { get; set; } = new();
}

[Owned]
public class Tag
{
    public string? Name { get; set; } = "n/a";

    public static bool TryParse(string? name, out Tag tag)
    {
        if (name is null)
        {
            tag = default!;
            return false;
        }

        tag = new Tag { Name = name };
        return true;
```

```
    }
}
```

The following code binds to an `int` array:

C#

```
// GET /todoitems/query-string-ids?ids=1&ids=3
app.MapGet("/todoitems/query-string-ids", async (int[] ids, TodoDb db) =>
{
    return await db.Todos
        .Where(t => ids.Contains(t.Id))
        .ToListAsync();
});
```

To test the preceding code, add the following endpoint to populate the database with `Todo` items:

C#

```
// POST /todoitems/batch
app.MapPost("/todoitems/batch", async (Todo[] todos, TodoDb db) =>
{
    await db.Todos.AddRangeAsync(todos);
    await db.SaveChangesAsync();

    return Results.Ok(todos);
});
```

Use a tool like HttpRepl to pass the following data to the previous endpoint:

C#

```
[
    {
        "id": 1,
        "name": "Have Breakfast",
        "isComplete": true,
        "tag": {
            "name": "home"
        }
    },
    {
        "id": 2,
        "name": "Have Lunch",
        "isComplete": true,
        "tag": {
            "name": "work"
        }
    },
```

```
    {
        "id": 3,
        "name": "Have Supper",
        "isComplete": true,
        "tag": {
            "name": "home"
        }
    },
    {
        "id": 4,
        "name": "Have Snacks",
        "isComplete": true,
        "tag": {
            "name": "N/A"
        }
    }
]
```

The following code binds to the header key `X-Todo-Id` and returns the `Todo` items with matching `Id` values:

C#

```
// GET /todoitems/header-ids
// The keys of the headers should all be X-Todo-Id with different values
app.MapGet("/todoitems/header-ids", async ([FromHeader(Name = "X-Todo-Id")]
int[] ids, TodoDb db) =>
{
    return await db.Todos
        .Where(t => ids.Contains(t.Id))
        .ToListAsync();
});
```

> ⓘ Note
>
> When binding a `string[]` from a query string, the absence of any matching query string value will result in an empty array instead of a null value.

Parameter binding for argument lists with [AsParameters]

AsParametersAttribute enables simple parameter binding to types and not complex or recursive model binding.

Consider the following code:

C#

```
using Microsoft.EntityFrameworkCore;
using TodoApi.Models;

var builder = WebApplication.CreateBuilder(args);
builder.Services.AddDatabaseDeveloperPageExceptionFilter();
builder.Services.AddDbContext<TodoDb>(opt =>
opt.UseInMemoryDatabase("TodoList"));
var app = builder.Build();

app.MapGet("/todoitems", async (TodoDb db) =>
    await db.Todos.Select(x => new TodoItemDTO(x)).ToListAsync());

app.MapGet("/todoitems/{id}",
                            async (int Id, TodoDb Db) =>
    await Db.Todos.FindAsync(Id)
        is Todo todo
            ? Results.Ok(new TodoItemDTO(todo))
            : Results.NotFound());
// Remaining code removed for brevity.
```

Consider the following `GET` endpoint:

C#

```
app.MapGet("/todoitems/{id}",
                            async (int Id, TodoDb Db) =>
    await Db.Todos.FindAsync(Id)
        is Todo todo
            ? Results.Ok(new TodoItemDTO(todo))
            : Results.NotFound());
```

The following `struct` can be used to replace the preceding highlighted parameters:

C#

```
struct TodoItemRequest
{
    public int Id { get; set; }
    public TodoDb Db { get; set; }
}
```

The refactored `GET` endpoint uses the preceding `struct` with the AsParameters attribute:

C#

```
app.MapGet("/ap/todoitems/{id}",
                                async ([AsParameters] TodoItemRequest
request) =>
```

```
    await request.Db.Todos.FindAsync(request.Id)
        is Todo todo
            ? Results.Ok(new TodoItemDTO(todo))
            : Results.NotFound());
```

The following code shows additional endpoints in the app:

C#

```
app.MapPost("/todoitems", async (TodoItemDTO Dto, TodoDb Db) =>
{
    var todoItem = new Todo
    {
        IsComplete = Dto.IsComplete,
        Name = Dto.Name
    };

    Db.Todos.Add(todoItem);
    await Db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todoItem.Id}", new
TodoItemDTO(todoItem));
});

app.MapPut("/todoitems/{id}", async (int Id, TodoItemDTO Dto, TodoDb Db) =>
{
    var todo = await Db.Todos.FindAsync(Id);

    if (todo is null) return Results.NotFound();

    todo.Name = Dto.Name;
    todo.IsComplete = Dto.IsComplete;

    await Db.SaveChangesAsync();

    return Results.NoContent();
});

app.MapDelete("/todoitems/{id}", async (int Id, TodoDb Db) =>
{
    if (await Db.Todos.FindAsync(Id) is Todo todo)
    {
        Db.Todos.Remove(todo);
        await Db.SaveChangesAsync();
        return Results.Ok(new TodoItemDTO(todo));
    }

    return Results.NotFound();
});
```

The following classes are used to refactor the parameter lists:

C#

```
class CreateTodoItemRequest
{
    public TodoItemDTO Dto { get; set; } = default!;
    public TodoDb Db { get; set; } = default!;
}

class EditTodoItemRequest
{
    public int Id { get; set; }
    public TodoItemDTO Dto { get; set; } = default!;
    public TodoDb Db { get; set; } = default!;
}
```

The following code shows the refactored endpoints using `AsParameters` and the preceding `struct` and classes:

C#

```
app.MapPost("/ap/todoitems", async ([AsParameters] CreateTodoItemRequest
request) =>
{
    var todoItem = new Todo
    {
        IsComplete = request.Dto.IsComplete,
        Name = request.Dto.Name
    };

    request.Db.Todos.Add(todoItem);
    await request.Db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todoItem.Id}", new
TodoItemDTO(todoItem));
});

app.MapPut("/ap/todoitems/{id}", async ([AsParameters] EditTodoItemRequest
request) =>
{
    var todo = await request.Db.Todos.FindAsync(request.Id);

    if (todo is null) return Results.NotFound();

    todo.Name = request.Dto.Name;
    todo.IsComplete = request.Dto.IsComplete;

    await request.Db.SaveChangesAsync();

    return Results.NoContent();
});

app.MapDelete("/ap/todoitems/{id}", async ([AsParameters] TodoItemRequest
```

```
request) =>
{
    if (await request.Db.Todos.FindAsync(request.Id) is Todo todo)
    {
        request.Db.Todos.Remove(todo);
        await request.Db.SaveChangesAsync();
        return Results.Ok(new TodoItemDTO(todo));
    }

    return Results.NotFound();
});
```

The following record types can be used to replace the preceding parameters:

C#

```
record TodoItemRequest(int Id, TodoDb Db);
record CreateTodoItemRequest(TodoItemDTO Dto, TodoDb Db);
record EditTodoItemRequest(int Id, TodoItemDTO Dto, TodoDb Db);
```

Using a `struct` with `AsParameters` can be more performant than using a `record` type.

The complete sample code in the AspNetCore.Docs.Samples repository.

Custom Binding

There are two ways to customize parameter binding:

1. For route, query, and header binding sources, bind custom types by adding a static `TryParse` method for the type.
2. Control the binding process by implementing a `BindAsync` method on a type.

TryParse

`TryParse` has two APIs:

C#

```
public static bool TryParse(string value, out T result);
public static bool TryParse(string value, IFormatProvider provider, out T
result);
```

The following code displays `Point: 12.3, 10.1` with the URI `/map?Point=12.3,10.1`:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

// GET /map?Point=12.3,10.1
app.MapGet("/map", (Point point) => $"Point: {point.X}, {point.Y}");

app.Run();

public class Point
{
    public double X { get; set; }
    public double Y { get; set; }

    public static bool TryParse(string? value, IFormatProvider? provider,
                                out Point? point)
    {
        // Format is "(12.3,10.1)"
        var trimmedValue = value?.TrimStart('(').TrimEnd(')');
        var segments = trimmedValue?.Split(',',
                StringSplitOptions.RemoveEmptyEntries |
StringSplitOptions.TrimEntries);
        if (segments?.Length == 2
            && double.TryParse(segments[0], out var x)
            && double.TryParse(segments[1], out var y))
        {
            point = new Point { X = x, Y = y };
            return true;
        }

        point = null;
        return false;
    }
}
```

BindAsync

`BindAsync` has the following APIs:

C#

```
public static ValueTask<T?> BindAsync(HttpContext context, ParameterInfo
parameter);
public static ValueTask<T?> BindAsync(HttpContext context);
```

The following code displays `SortBy:xyz, SortDirection:Desc, CurrentPage:99` with the URI `/products?SortBy=xyz&SortDir=Desc&Page=99`:

C#

```
using System.Reflection;

var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

// GET /products?SortBy=xyz&SortDir=Desc&Page=99
app.MapGet("/products", (PagingData pageData) => $"SortBy:{pageData.SortBy},
" +
       $"SortDirection:{pageData.SortDirection}, CurrentPage:
{pageData.CurrentPage}");

app.Run();

public class PagingData
{
    public string? SortBy { get; init; }
    public SortDirection SortDirection { get; init; }
    public int CurrentPage { get; init; } = 1;

    public static ValueTask<PagingData?> BindAsync(HttpContext context,
                                                   ParameterInfo parameter)
    {
        const string sortByKey = "sortBy";
        const string sortDirectionKey = "sortDir";
        const string currentPageKey = "page";

        Enum.TryParse<SortDirection>
(context.Request.Query[sortDirectionKey],
                                     ignoreCase: true, out var
sortDirection);
        int.TryParse(context.Request.Query[currentPageKey], out var page);
        page = page == 0 ? 1 : page;

        var result = new PagingData
        {
            SortBy = context.Request.Query[sortByKey],
            SortDirection = sortDirection,
            CurrentPage = page
        };

        return ValueTask.FromResult<PagingData?>(result);
    }
}

public enum SortDirection
{
    Default,
    Asc,
    Desc
}
```

Binding failures

When binding fails, the framework logs a debug message and returns various status codes to the client depending on the failure mode.

Expand table

Failure mode	Nullable Parameter Type	Binding Source	Status code
`{ParameterType}.TryParse` returns `false`	yes	route/query/header	400
`{ParameterType}.BindAsync` returns `null`	yes	custom	400
`{ParameterType}.BindAsync` throws	doesn't matter	custom	500
Failure to deserialize JSON body	doesn't matter	body	400
Wrong content type (not `application/json`)	doesn't matter	body	415

Binding Precedence

The rules for determining a binding source from a parameter:

1. Explicit attribute defined on parameter (From* attributes) in the following order:
   a. Route values: [FromRoute]
   b. Query string: [FromQuery]
   c. Header: [FromHeader]
   d. Body: [FromBody]
   e. Form: [FromForm]
   f. Service: [FromServices]
   g. Parameter values: [AsParameters]
2. Special types
   a. HttpContext
   b. HttpRequest (HttpContext.Request)
   c. HttpResponse (HttpContext.Response)
   d. ClaimsPrincipal (HttpContext.User)
   e. CancellationToken (HttpContext.RequestAborted)
   f. IFormCollection (HttpContext.Request.Form)
   g. IFormFileCollection (HttpContext.Request.Form.Files)
   h. IFormFile (HttpContext.Request.Form.Files[paramName])
   i. Stream (HttpContext.Request.Body)
   j. PipeReader (HttpContext.Request.BodyReader)

3. Parameter type has a valid static BindAsync method.
4. Parameter type is a string or has a valid static TryParse method.
   a. If the parameter name exists in the route template for example, `app.Map("/todo/{id}", (int id) => {});`, then it's bound from the route.
   b. Bound from the query string.
5. If the parameter type is a service provided by dependency injection, it uses that service as the source.
6. The parameter is from the body.

Configure JSON deserialization options for body binding

The body binding source uses System.Text.Json for deserialization. It is ***not*** possible to change this default, but JSON serialization and deserialization options can be configured.

Configure JSON deserialization options globally

Options that apply globally for an app can be configured by invoking ConfigureHttpJsonOptions. The following example includes public fields and formats JSON output.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options => {
    options.SerializerOptions.WriteIndented = true;
    options.SerializerOptions.IncludeFields = true;
});

var app = builder.Build();

app.MapPost("/", (Todo todo) => {
    if (todo is not null) {
        todo.Name = todo.NameField;
    }
    return todo;
});

app.Run();

class Todo {
    public string? Name { get; set; }
    public string? NameField;
    public bool IsComplete { get; set; }
}
// If the request body contains the following JSON:
```

```
//
// {"nameField":"Walk dog", "isComplete":false}
//
// The endpoint returns the following JSON:
//
// {
//    "name":"Walk dog",
//    "nameField":"Walk dog",
//    "isComplete":false
// }
```

Since the sample code configures both serialization and deserialization, it can read `NameField` and include `NameField` in the output JSON.

Configure JSON deserialization options for an endpoint

ReadFromJsonAsync has overloads that accept a JsonSerializerOptions object. The following example includes public fields and formats JSON output.

C#

```
using System.Text.Json;

var app = WebApplication.Create();

var options = new JsonSerializerOptions(JsonSerializerDefaults.Web) {
    IncludeFields = true,
    WriteIndented = true
};

app.MapPost("/", async (HttpContext context) => {
    if (context.Request.HasJsonContentType()) {
        var todo = await context.Request.ReadFromJsonAsync<Todo>(options);
        if (todo is not null) {
            todo.Name = todo.NameField;
        }
        return Results.Ok(todo);
    }
    else {
        return Results.BadRequest();
    }
});

app.Run();

class Todo
{
    public string? Name { get; set; }
    public string? NameField;
    public bool IsComplete { get; set; }
}
```

```
// If the request body contains the following JSON:
//
// {"nameField":"Walk dog", "isComplete":false}
//
// The endpoint returns the following JSON:
//
// {
//    "name":"Walk dog",
//    "isComplete":false
// }
```

Since the preceding code applies the customized options only to deserialization, the output JSON excludes `NameField`.

Read the request body

Read the request body directly using a HttpContext or HttpRequest parameter:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapPost("/uploadstream", async (IConfiguration config, HttpRequest
request) =>
{
    var filePath = Path.Combine(config["StoredFilesPath"],
Path.GetRandomFileName());

    await using var writeStream = File.Create(filePath);
    await request.BodyReader.CopyToAsync(writeStream);
});

app.Run();
```

The preceding code:

- Accesses the request body using HttpRequest.BodyReader.
- Copies the request body to a local file.

How to create responses in Minimal API apps

Article • 08/07/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Minimal endpoints support the following types of return values:

1. `string` - This includes `Task<string>` and `ValueTask<string>`.
2. `T` (Any other type) - This includes `Task<T>` and `ValueTask<T>`.
3. `IResult` based - This includes `Task<IResult>` and `ValueTask<IResult>`.

`string` return values

Expand table

Behavior	Content-Type
The framework writes the string directly to the response.	`text/plain`

Consider the following route handler, which returns a `Hello world` text.

C#

```
app.MapGet("/hello", () => "Hello World");
```

The `200` status code is returned with `text/plain` Content-Type header and the following content.

text

```
Hello World
```

`T` (Any other type) return values

Expand table

Behavior	Content-Type
The framework JSON-serializes the response.	`application/json`

Consider the following route handler, which returns an anonymous type containing a `Message` string property.

C#

```
app.MapGet("/hello", () => new { Message = "Hello World" });
```

The `200` status code is returned with `application/json` Content-Type header and the following content.

JSON

```
{"message":"Hello World"}
```

`IResult` return values

Expand table

Behavior	Content-Type
The framework calls IResult.ExecuteAsync.	Decided by the `IResult` implementation.

The `IResult` interface defines a contract that represents the result of an HTTP endpoint. The static Results class and the static TypedResults are used to create various `IResult` objects that represent different types of responses.

TypedResults vs Results

The Results and TypedResults static classes provide similar sets of results helpers. The `TypedResults` class is the *typed* equivalent of the `Results` class. However, the `Results` helpers' return type is IResult, while each `TypedResults` helper's return type is one of the `IResult` implementation types. The difference means that for `Results` helpers a conversion is needed when the concrete type is needed, for example, for unit testing.

The implementation types are defined in the Microsoft.AspNetCore.Http.HttpResults namespace.

Returning `TypedResults` rather than `Results` has the following advantages:

- `TypedResults` helpers return strongly typed objects, which can improve code readability, unit testing, and reduce the chance of runtime errors.
- The implementation type automatically provides the response type metadata for OpenAPI to describe the endpoint.

Consider the following endpoint, for which a `200 OK` status code with the expected JSON response is produced.

C#

```
app.MapGet("/hello", () => Results.Ok(new Message() { Text = "Hello World!"
}))
    .Produces<Message>();
```

In order to document this endpoint correctly the extensions method `Produces` is called. However, it's not necessary to call `Produces` if `TypedResults` is used instead of `Results`, as shown in the following code. `TypedResults` automatically provides the metadata for the endpoint.

C#

```
app.MapGet("/hello2", () => TypedResults.Ok(new Message() { Text = "Hello
World!" }));
```

For more information about describing a response type, see OpenAPI support in minimal APIs.

As mentioned previously, when using `TypedResults`, a conversion is not needed. Consider the following minimal API which returns a `TypedResults` class

C#

```
public static async Task<Ok<Todo[]>> GetAllTodos(TodoGroupDbContext
database)
{
    var todos = await database.Todos.ToArrayAsync();
    return TypedResults.Ok(todos);
}
```

The following test checks for the full concrete type:

C#

```
[Fact]
public async Task GetAllReturnsTodosFromDatabase()
{
    // Arrange
    await using var context = new MockDb().CreateDbContext();

    context.Todos.Add(new Todo
    {
        Id = 1,
        Title = "Test title 1",
        Description = "Test description 1",
        IsDone = false
    });

    context.Todos.Add(new Todo
    {
        Id = 2,
        Title = "Test title 2",
        Description = "Test description 2",
        IsDone = true
    });

    await context.SaveChangesAsync();

    // Act
    var result = await TodoEndpointsV1.GetAllTodos(context);

    //Assert
    Assert.IsType<Ok<Todo[]>>(result);

    Assert.NotNull(result.Value);
    Assert.NotEmpty(result.Value);
    Assert.Collection(result.Value, todo1 =>
    {
        Assert.Equal(1, todo1.Id);
        Assert.Equal("Test title 1", todo1.Title);
        Assert.False(todo1.IsDone);
    }, todo2 =>
    {
        Assert.Equal(2, todo2.Id);
        Assert.Equal("Test title 2", todo2.Title);
        Assert.True(todo2.IsDone);
    });
}
```

Because all methods on `Results` return `IResult` in their signature, the compiler automatically infers that as the request delegate return type when returning different results from a single endpoint. `TypedResults` requires the use of `Results<T1, TN>` from such delegates.

The following method compiles because both Results.Ok and Results.NotFound are declared as returning `IResult`, even though the actual concrete types of the objects returned are different:

```
C#

app.MapGet("/todoitems/{id}", async (int id, TodoDb db) =>
    await db.Todos.FindAsync(id)
        is Todo todo
            ? Results.Ok(todo)
            : Results.NotFound());
```

The following method does not compile, because `TypedResults.Ok` and `TypedResults.NotFound` are declared as returning different types and the compiler won't attempt to infer the best matching type:

```
C#

app.MapGet("/todoitems/{id}", async (int id, TodoDb db) =>
     await db.Todos.FindAsync(id)
     is Todo todo
        ? TypedResults.Ok(todo)
        : TypedResults.NotFound());
```

To use `TypedResults`, the return type must be fully declared, which when asynchronous requires the `Task<>` wrapper. Using `TypedResults` is more verbose, but that's the trade-off for having the type information be statically available and thus capable of self-describing to OpenAPI:

```
C#

app.MapGet("/todoitems/{id}", async Task<Results<Ok<Todo>, NotFound>> (int
id, TodoDb db) =>
   await db.Todos.FindAsync(id)
    is Todo todo
       ? TypedResults.Ok(todo)
       : TypedResults.NotFound());
```

Results<TResult1, TResultN>

Use Results<TResult1, TResultN> as the endpoint handler return type instead of `IResult` when:

- Multiple `IResult` implementation types are returned from the endpoint handler.

- The static `TypedResult` class is used to create the `IResult` objects.

This alternative is better than returning `IResult` because the generic union types automatically retain the endpoint metadata. And since the `Results<TResult1, TResultN>` union types implement implicit cast operators, the compiler can automatically convert the types specified in the generic arguments to an instance of the union type.

This has the added benefit of providing compile-time checking that a route handler actually only returns the results that it declares it does. Attempting to return a type that isn't declared as one of the generic arguments to `Results<>` results in a compilation error.

Consider the following endpoint, for which a `400 BadRequest` status code is returned when the `orderId` is greater than `999`. Otherwise, it produces a `200 OK` with the expected content.

C#

```
app.MapGet("/orders/{orderId}", IResult (int orderId)
    => orderId > 999 ? TypedResults.BadRequest() : TypedResults.Ok(new
Order(orderId)))
    .Produces(400)
    .Produces<Order>();
```

In order to document this endpoint correctly the extension method `Produces` is called. However, since the `TypedResults` helper automatically includes the metadata for the endpoint, you can return the `Results<T1, Tn>` union type instead, as shown in the following code.

C#

```
app.MapGet("/orders/{orderId}", Results<BadRequest, Ok<Order>> (int orderId)
    => orderId > 999 ? TypedResults.BadRequest() : TypedResults.Ok(new
Order(orderId)));
```

Built-in results

Common result helpers exist in the Results and TypedResults static classes. Returning `TypedResults` is preferred to returning `Results`. For more information, see TypedResults vs Results.

The following sections demonstrate the usage of the common result helpers.

JSON

```C#
app.MapGet("/hello", () => Results.Json(new { Message = "Hello World" }));
```

WriteAsJsonAsync is an alternative way to return JSON:

```C#
app.MapGet("/", (HttpContext context) => context.Response.WriteAsJsonAsync
    (new { Message = "Hello World" }));
```

Custom Status Code

```C#
app.MapGet("/405", () => Results.StatusCode(405));
```

Internal Server Error

```C#
app.MapGet("/500", () => Results.InternalServerError("Something went
wrong!"));
```

The preceding example returns a 500 status code.

Text

```C#
app.MapGet("/text", () => Results.Text("This is some text"));
```

Stream

```C#
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

var proxyClient = new HttpClient();
```

```
app.MapGet("/pokemon", async () =>
{
    var stream = await
proxyClient.GetStreamAsync("http://contoso/pokedex.json");
    // Proxy the response as JSON
    return Results.Stream(stream, "application/json");
});

app.Run();
```

Results.Stream overloads allow access to the underlying HTTP response stream without buffering. The following example uses ImageSharp to return a reduced size of the specified image:

C#

```
using SixLabors.ImageSharp;
using SixLabors.ImageSharp.Formats.Jpeg;
using SixLabors.ImageSharp.Processing;

var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/process-image/{strImage}", (string strImage, HttpContext http,
CancellationToken token) =>
{
    http.Response.Headers.CacheControl = $"public,max-age=
{TimeSpan.FromHours(24).TotalSeconds}";
    return Results.Stream(stream => ResizeImageAsync(strImage, stream,
token), "image/jpeg");
});

async Task ResizeImageAsync(string strImage, Stream stream,
CancellationToken token)
{
    var strPath = $"wwwroot/img/{strImage}";
    using var image = await Image.LoadAsync(strPath, token);
    int width = image.Width / 2;
    int height = image.Height / 2;
    image.Mutate(x =>x.Resize(width, height));
    await image.SaveAsync(stream, JpegFormat.Instance, cancellationToken:
token);
}
```

The following example streams an image from Azure Blob storage:

C#

```
app.MapGet("/stream-image/{containerName}/{blobName}",
    async (string blobName, string containerName, CancellationToken token)
```

```
=>
{
    var conStr = builder.Configuration["blogConStr"];
    BlobContainerClient blobContainerClient = new
BlobContainerClient(conStr, containerName);
    BlobClient blobClient = blobContainerClient.GetBlobClient(blobName);
    return Results.Stream(await blobClient.OpenReadAsync(cancellationToken:
token), "image/jpeg");
});
```

The following example streams a video from an Azure Blob:

C#

```
// GET /stream-video/videos/earth.mp4
app.MapGet("/stream-video/{containerName}/{blobName}",
     async (HttpContext http, CancellationToken token, string blobName,
string containerName) =>
{
    var conStr = builder.Configuration["blogConStr"];
    BlobContainerClient blobContainerClient = new
BlobContainerClient(conStr, containerName);
    BlobClient blobClient = blobContainerClient.GetBlobClient(blobName);

    var properties = await blobClient.GetPropertiesAsync(cancellationToken:
token);

    DateTimeOffset lastModified = properties.Value.LastModified;
    long length = properties.Value.ContentLength;

    long etagHash = lastModified.ToFileTime() ^ length;
    var entityTag = new EntityTagHeaderValue('\"' +
Convert.ToString(etagHash, 16) + '\"');

    http.Response.Headers.CacheControl = $"public,max-age=
{TimeSpan.FromHours(24).TotalSeconds}";

    return Results.Stream(await blobClient.OpenReadAsync(cancellationToken:
token),
        contentType: "video/mp4",
        lastModified: lastModified,
        entityTag: entityTag,
        enableRangeProcessing: true);
});
```

Redirect

C#

```
app.MapGet("/old-path", () => Results.Redirect("/new-path"));
```

File

```
C#
```

```
app.MapGet("/download", () => Results.File("myfile.text"));
```

HttpResult interfaces

The following interfaces in the Microsoft.AspNetCore.Http namespace provide a way to detect the `IResult` type at runtime, which is a common pattern in filter implementations:

- IContentTypeHttpResult
- IFileHttpResult
- INestedHttpResult
- IStatusCodeHttpResult
- IValueHttpResult
- IValueHttpResult<TValue>

Here's an example of a filter that uses one of these interfaces:

```
C#
```

```
app.MapGet("/weatherforecast", (int days) =>
{
    if (days <= 0)
    {
        return Results.BadRequest();
    }

    var forecast = Enumerable.Range(1, days).Select(index =>
       new WeatherForecast(DateTime.Now.AddDays(index),
Random.Shared.Next(-20, 55), "Cool"))
        .ToArray();
    return Results.Ok(forecast);
}).
AddEndpointFilter(async (context, next) =>
{
    var result = await next(context);

    return result switch
    {
        IValueHttpResult<WeatherForecast[]> weatherForecastResult => new
WeatherHttpResult(weatherForecastResult.Value),
        _ => result
    };
});
```

For more information, see Filters in Minimal API apps and IResult implementation types.

Customizing responses

Applications can control responses by implementing a custom IResult type. The following code is an example of an HTML result type:

C#

```
using System.Net.Mime;
using System.Text;
static class ResultsExtensions
{
    public static IResult Html(this IResultExtensions resultExtensions,
string html)
    {
        ArgumentNullException.ThrowIfNull(resultExtensions);

        return new HtmlResult(html);
    }
}

class HtmlResult : IResult
{
    private readonly string _html;

    public HtmlResult(string html)
    {
        _html = html;
    }

    public Task ExecuteAsync(HttpContext httpContext)
    {
        httpContext.Response.ContentType = MediaTypeNames.Text.Html;
        httpContext.Response.ContentLength =
Encoding.UTF8.GetByteCount(_html);
        return httpContext.Response.WriteAsync(_html);
    }
}
```

We recommend adding an extension method to Microsoft.AspNetCore.Http.IResultExtensions to make these custom results more discoverable.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/html", () => Results.Extensions.Html(@$"<!doctype html>
```

```
<html>
    <head><title>miniHTML</title></head>
    <body>
        <h1>Hello World</h1>
        <p>The time on the server is {DateTime.Now:O}</p>
    </body>
</html>"));

app.Run();
```

Also, a custom `IResult` type can provide its own annotation by implementing the IEndpointMetadataProvider interface. For example, the following code adds an annotation to the preceding `HtmlResult` type that describes the response produced by the endpoint.

C#

```
class HtmlResult : IResult, IEndpointMetadataProvider
{
    private readonly string _html;

    public HtmlResult(string html)
    {
        _html = html;
    }

    public Task ExecuteAsync(HttpContext httpContext)
    {
        httpContext.Response.ContentType = MediaTypeNames.Text.Html;
        httpContext.Response.ContentLength =
Encoding.UTF8.GetByteCount(_html);
        return httpContext.Response.WriteAsync(_html);
    }

    public static void PopulateMetadata(MethodInfo method, EndpointBuilder
builder)
    {
        builder.Metadata.Add(new ProducesHtmlMetadata());
    }
}
```

The `ProducesHtmlMetadata` is an implementation of IProducesResponseTypeMetadata that defines the produced response content type `text/html` and the status code `200 OK`.

C#

```
internal sealed class ProducesHtmlMetadata : IProducesResponseTypeMetadata
{
    public Type? Type => null;
```

```
    public int StatusCode => 200;

    public IEnumerable<string> ContentTypes { get; } = new[] {
MediaTypeNames.Text.Html };
}
```

An alternative approach is using the Microsoft.AspNetCore.Mvc.ProducesAttribute to describe the produced response. The following code changes the `PopulateMetadata` method to use `ProducesAttribute`.

C#

```
public static void PopulateMetadata(MethodInfo method, EndpointBuilder
builder)
{
    builder.Metadata.Add(new ProducesAttribute(MediaTypeNames.Text.Html));
}
```

Configure JSON serialization options

By default, minimal API apps use Web defaults options during JSON serialization and deserialization.

Configure JSON serialization options globally

Options can be configured globally for an app by invoking ConfigureHttpJsonOptions. The following example includes public fields and formats JSON output.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.ConfigureHttpJsonOptions(options => {
    options.SerializerOptions.WriteIndented = true;
    options.SerializerOptions.IncludeFields = true;
});

var app = builder.Build();

app.MapPost("/", (Todo todo) => {
    if (todo is not null) {
        todo.Name = todo.NameField;
    }
    return todo;
});

app.Run();
```

```
class Todo {
    public string? Name { get; set; }
    public string? NameField;
    public bool IsComplete { get; set; }
}
// If the request body contains the following JSON:
//
// {"nameField":"Walk dog", "isComplete":false}
//
// The endpoint returns the following JSON:
//
// {
//    "name":"Walk dog",
//    "nameField":"Walk dog",
//    "isComplete":false
// }
```

Since fields are included, the preceding code reads `NameField` and includes it in the output JSON.

Configure JSON serialization options for an endpoint

To configure serialization options for an endpoint, invoke Results.Json and pass to it a JsonSerializerOptions object, as shown in the following example:

C#

```
using System.Text.Json;

var app = WebApplication.Create();

var options = new JsonSerializerOptions(JsonSerializerDefaults.Web)
    { WriteIndented = true };

app.MapGet("/", () =>
    Results.Json(new Todo { Name = "Walk dog", IsComplete = false },
options));

app.Run();

class Todo
{
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
// The endpoint returns the following JSON:
//
// {
//   "name":"Walk dog",
```

```
//   "isComplete":false
// }
```

As an alternative, use an overload of WriteAsJsonAsync that accepts a JsonSerializerOptions object. The following example uses this overload to format the output JSON:

C#

```
using System.Text.Json;

var app = WebApplication.Create();

var options = new JsonSerializerOptions(JsonSerializerDefaults.Web) {
    WriteIndented = true };

app.MapGet("/", (HttpContext context) =>
    context.Response.WriteAsJsonAsync<Todo>(
        new Todo { Name = "Walk dog", IsComplete = false }, options));

app.Run();

class Todo
{
    public string? Name { get; set; }
    public bool IsComplete { get; set; }
}
// The endpoint returns the following JSON:
//
// {
//   "name":"Walk dog",
//   "isComplete":false
// }
```

Filters in Minimal API apps

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

By Fiyaz Bin Hasan, Martin Costello, and Rick Anderson

Minimal API filters allow developers to implement business logic that supports:

- Running code before and after the endpoint handler.
- Inspecting and modifying parameters provided during an endpoint handler invocation.
- Intercepting the response behavior of an endpoint handler.

Filters can be helpful in the following scenarios:

- Validating the request parameters and body that are sent to an endpoint.
- Logging information about the request and response.
- Validating that a request is targeting a supported API version.

Filters can be registered by providing a Delegate that takes a EndpointFilterInvocationContext and returns a EndpointFilterDelegate. The `EndpointFilterInvocationContext` provides access to the `HttpContext` of the request and an `Arguments` list indicating the arguments passed to the handler in the order in which they appear in the declaration of the handler.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

string ColorName(string color) => $"Color specified: {color}!";

app.MapGet("/colorSelector/{color}", ColorName)
    .AddEndpointFilter(async (invocationContext, next) =>
    {
        var color = invocationContext.GetArgument<string>(0);
```

```
        if (color == "Red")
        {
            return Results.Problem("Red not allowed!");
        }
        return await next(invocationContext);
    });

app.Run();
```

The preceding code:

- Calls the `AddEndpointFilter` extension method to add a filter to the `/colorSelector/{color}` endpoint.
- Returns the color specified except for the value `"Red"`.
- Returns Results.Problem when the `/colorSelector/Red` is requested.
- Uses `next` as the `EndpointFilterDelegate` and `invocationContext` as the `EndpointFilterInvocationContext` to invoke the next filter in the pipeline or the request delegate if the last filter has been invoked.

The filter is run before the endpoint handler. When multiple `AddEndpointFilter` invocations are made on a handler:

- Filter code called before the `EndpointFilterDelegate` (`next`) is called are executed in order of First In, First Out (FIFO) order.
- Filter code called after the `EndpointFilterDelegate` (`next`) is called are executed in order of First In, Last Out (FILO) order.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/", () =>
    {
        app.Logger.LogInformation("             Endpoint");
        return "Test of multiple filters";
    })
    .AddEndpointFilter(async (efiContext, next) =>
    {
        app.Logger.LogInformation("Before first filter");
        var result = await next(efiContext);
        app.Logger.LogInformation("After first filter");
        return result;
    })
    .AddEndpointFilter(async (efiContext, next) =>
    {
```

```
        app.Logger.LogInformation(" Before 2nd filter");
        var result = await next(efiContext);
        app.Logger.LogInformation(" After 2nd filter");
        return result;
    })
    .AddEndpointFilter(async (efiContext, next) =>
    {
        app.Logger.LogInformation("     Before 3rd filter");
        var result = await next(efiContext);
        app.Logger.LogInformation("     After 3rd filter");
        return result;
    });

app.Run();
```

In the preceding code, the filters and endpoint log the following output:

.NET CLI

```
Before first filter
    Before 2nd filter
        Before 3rd filter
            Endpoint
        After 3rd filter
    After 2nd filter
After first filter
```

The following code uses filters that implement the `IEndpointFilter` interface:

C#

```
using Filters.EndpointFilters;

var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapGet("/", () =>
    {
        app.Logger.LogInformation("Endpoint");
        return "Test of multiple filters";
    })
    .AddEndpointFilter<AEndpointFilter>()
    .AddEndpointFilter<BEndpointFilter>()
    .AddEndpointFilter<CEndpointFilter>();

app.Run();
```

In the preceding code, the filters and handlers logs show the order they are run:

.NET CLI

```
AEndpointFilter Before next
BEndpointFilter Before next
CEndpointFilter Before next
      Endpoint
CEndpointFilter After next
BEndpointFilter After next
AEndpointFilter After next
```

Filters implementing the `IEndpointFilter` interface are shown in the following example:

C#

```
namespace Filters.EndpointFilters;

public abstract class ABCEndpointFilters : IEndpointFilter
{
    protected readonly ILogger Logger;
    private readonly string _methodName;

    protected ABCEndpointFilters(ILoggerFactory loggerFactory)
    {
        Logger = loggerFactory.CreateLogger<ABCEndpointFilters>();
        _methodName = GetType().Name;
    }

    public virtual async ValueTask<object?>
InvokeAsync(EndpointFilterInvocationContext context,
        EndpointFilterDelegate next)
    {
        Logger.LogInformation("{MethodName} Before next", _methodName);
        var result = await next(context);
        Logger.LogInformation("{MethodName} After next", _methodName);
        return result;
    }
}

class AEndpointFilter : ABCEndpointFilters
{
    public AEndpointFilter(ILoggerFactory loggerFactory) :
base(loggerFactory) { }
}

class BEndpointFilter : ABCEndpointFilters
{
    public BEndpointFilter(ILoggerFactory loggerFactory) :
base(loggerFactory) { }
}

class CEndpointFilter : ABCEndpointFilters
{
```

```
    public CEndpointFilter(ILoggerFactory loggerFactory) :
base(loggerFactory) { }
}
```

Validate an object with a filter

Consider a filter that validates a `Todo` object:

C#

```
app.MapPut("/todoitems/{id}", async (Todo inputTodo, int id, TodoDb db) =>
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
}).AddEndpointFilter(async (efiContext, next) =>
{
    var tdparam = efiContext.GetArgument<Todo>(0);

    var validationError = Utilities.IsValid(tdparam);

    if (!string.IsNullOrEmpty(validationError))
    {
        return Results.Problem(validationError);
    }
    return await next(efiContext);
});
```

In the preceding code:

- The `EndpointFilterInvocationContext` object provides access to the parameters associated with a particular request issued to the endpoint via the `GetArguments` method.
- The filter is registered using a `delegate` that takes a `EndpointFilterInvocationContext` and returns a `EndpointFilterDelegate`.

In addition to being passed as delegates, filters can be registered by implementing the `IEndpointFilter` interface. The following code shows the preceding filter encapsulated in a class which implements `IEndpointFilter`:

C#

```
public class TodoIsValidFilter : IEndpointFilter
{
    private ILogger _logger;

    public TodoIsValidFilter(ILoggerFactory loggerFactory)
    {
        _logger = loggerFactory.CreateLogger<TodoIsValidFilter>();
    }

    public async ValueTask<object?>
InvokeAsync(EndpointFilterInvocationContext efiContext,
        EndpointFilterDelegate next)
    {
        var todo = efiContext.GetArgument<Todo>(0);

        var validationError = Utilities.IsValid(todo!);

        if (!string.IsNullOrEmpty(validationError))
        {
            _logger.LogWarning(validationError);
            return Results.Problem(validationError);
        }
        return await next(efiContext);
    }
}
```

Filters that implement the `IEndpointFilter` interface can resolve dependencies from Dependency Injection(DI), as shown in the previous code. Although filters can resolve dependencies from DI, filters themselves can ***not*** be resolved from DI.

The `ToDoIsValidFilter` is applied to the following endpoints:

C#

```
app.MapPut("/todoitems2/{id}", async (Todo inputTodo, int id, TodoDb db) =>
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();

    return Results.NoContent();
}).AddEndpointFilter<TodoIsValidFilter>();

app.MapPost("/todoitems", async (Todo todo, TodoDb db) =>
{
```

```
    db.Todos.Add(todo);
    await db.SaveChangesAsync();

    return Results.Created($"/todoitems/{todo.Id}", todo);
}).AddEndpointFilter<TodoIsValidFilter>();
```

The following filter validates the `Todo` object and modifies the `Name` property:

C#

```
public class TodoIsValidUcFilter : IEndpointFilter
{
    public async ValueTask<object?>
InvokeAsync(EndpointFilterInvocationContext efiContext,
        EndpointFilterDelegate next)
    {
        var todo = efiContext.GetArgument<Todo>(0);
        todo.Name = todo.Name!.ToUpper();

        var validationError = Utilities.IsValid(todo!);

        if (!string.IsNullOrEmpty(validationError))
        {
            return Results.Problem(validationError);
        }
        return await next(efiContext);
    }
}
```

Register a filter using an endpoint filter factory

In some scenarios, it might be necessary to cache some of the information provided in the MethodInfo in a filter. For example, let's assume that we wanted to verify that the handler an endpoint filter is attached to has a first parameter that evaluates to a `Todo` type.

C#

```
app.MapPut("/todoitems/{id}", async (Todo inputTodo, int id, TodoDb db) =>
{
    var todo = await db.Todos.FindAsync(id);

    if (todo is null) return Results.NotFound();

    todo.Name = inputTodo.Name;
    todo.IsComplete = inputTodo.IsComplete;

    await db.SaveChangesAsync();
```

```
    return Results.NoContent();
}).AddEndpointFilterFactory((filterFactoryContext, next) =>
{
    var parameters = filterFactoryContext.MethodInfo.GetParameters();
    if (parameters.Length >= 1 && parameters[0].ParameterType ==
typeof(Todo))
    {
        return async invocationContext =>
        {
            var todoParam = invocationContext.GetArgument<Todo>(0);

            var validationError = Utilities.IsValid(todoParam);

            if (!string.IsNullOrEmpty(validationError))
            {
                return Results.Problem(validationError);
            }
            return await next(invocationContext);
        };
    }
    return invocationContext => next(invocationContext);
});
```

In the preceding code:

- The `EndpointFilterFactoryContext` object provides access to the MethodInfo associated with the endpoint's handler.
- The signature of the handler is examined by inspecting `MethodInfo` for the expected type signature. If the expected signature is found, the validation filter is registered onto the endpoint. This factory pattern is useful to register a filter that depends on the signature of the target endpoint handler.
- If a matching signature isn't found, then a pass-through filter is registered.

Register a filter on controller actions

In some scenarios, it might be necessary to apply the same filter logic for both route-handler based endpoints and controller actions. For this scenario, it is possible to invoke `AddEndpointFilter` on `ControllerActionEndpointConventionBuilder` to support executing the same filter logic on actions and endpoints.

C#

```
var builder = WebApplication.CreateBuilder(args);

var app = builder.Build();

app.MapController()
    .AddEndpointFilter(async (efiContext, next) =>
```

```
    {
        efiContext.HttpContext.Items["endpointFilterCalled"] = true;
        var result = await next(efiContext);
        return result;
    });

app.Run();
```

Unit and integration tests in Minimal API apps

Article • 07/26/2024

> **Important**
>

>
> For the current release, see the .NET 8 version of this article.

By Fiyaz Bin Hasan, and Rick Anderson

Introduction to integration tests

Integration tests evaluate an app's components on a broader level than unit tests. Unit tests are used to test isolated software components, such as individual class methods. Integration tests confirm that two or more app components work together to produce an expected result, possibly including every component required to fully process a request.

These broader tests are used to test the app's infrastructure and whole framework, often including the following components:

- Database
- File system
- Network appliances
- Request-response pipeline

Unit tests use fabricated components, known as *fakes* or *mock objects*, in place of infrastructure components.

In contrast to unit tests, integration tests:

- Use the actual components that the app uses in production.
- Require more code and data processing.
- Take longer to run.

Therefore, limit the use of integration tests to the most important infrastructure scenarios. If a behavior can be tested using either a unit test or an integration test,

choose the unit test.

In discussions of integration tests, the tested project is frequently called the ***System Under Test***, or "**SUT**" for short. "SUT" is used throughout this article to refer to the ASP.NET Core app being tested.

Don't write integration tests for every permutation of data and file access with databases and file systems. Regardless of how many places across an app interact with databases and file systems, a focused set of read, write, update, and delete integration tests are usually capable of adequately testing database and file system components. Use unit tests for routine tests of method logic that interact with these components. In unit tests, the use of infrastructure fakes or mocks result in faster test execution.

ASP.NET Core integration tests

Integration tests in ASP.NET Core require the following:

- A test project is used to contain and execute the tests. The test project has a reference to the SUT.
- The test project creates a test web host for the SUT and uses a test server client to handle requests and responses with the SUT.
- A test runner is used to execute the tests and report the test results.

Integration tests follow a sequence of events that include the usual *Arrange*, *Act*, and *Assert* test steps:

1. The SUT's web host is configured.
2. A test server client is created to submit requests to the app.
3. The *Arrange* test step is executed: The test app prepares a request.
4. The *Act* test step is executed: The client submits the request and receives the response.
5. The *Assert* test step is executed: The *actual* response is validated as a *pass* or *fail* based on an *expected* response.
6. The process continues until all of the tests are executed.
7. The test results are reported.

Usually, the test web host is configured differently than the app's normal web host for the test runs. For example, a different database or different app settings might be used for the tests.

Infrastructure components, such as the test web host and in-memory test server (TestServer), are provided or managed by the Microsoft.AspNetCore.Mvc.Testing package. Use of this package streamlines test creation and execution.

The `Microsoft.AspNetCore.Mvc.Testing` package handles the following tasks:

- Copies the dependencies file (`.deps`) from the SUT into the test project's `bin` directory.
- Sets the content root to the SUT's project root so that static files and pages/views are found when the tests are executed.
- Provides the WebApplicationFactory class to streamline bootstrapping the SUT with `TestServer`.

The unit tests documentation describes how to set up a test project and test runner, along with detailed instructions on how to run tests and recommendations for how to name tests and test classes.

Separate unit tests from integration tests into different projects. Separating the tests:

- Helps ensure that infrastructure testing components aren't accidentally included in the unit tests.
- Allows control over which set of tests are run.

The sample code on GitHub provides an example of unit and integration tests on a Minimal API app.

IResult implementation types

Public IResult implementation types in the Microsoft.AspNetCore.Http.HttpResults namespace can be used to unit test minimal route handlers when using named methods instead of lambdas.

The following code uses the NotFound<TValue> class:

C#

```
[Fact]
public async Task GetTodoReturnsNotFoundIfNotExists()
{
    // Arrange
    await using var context = new MockDb().CreateDbContext();

    // Act
    var result = await TodoEndpointsV1.GetTodo(1, context);

    //Assert
    Assert.IsType<Results<Ok<Todo>, NotFound>>(result);

    var notFoundResult = (NotFound) result.Result;
```

```
    Assert.NotNull(notFoundResult);
}
```

The following code uses the Ok<TValue> class:

C#

```
[Fact]
public async Task GetTodoReturnsTodoFromDatabase()
{
    // Arrange
    await using var context = new MockDb().CreateDbContext();

    context.Todos.Add(new Todo
    {
        Id = 1,
        Title = "Test title",
        Description = "Test description",
        IsDone = false
    });

    await context.SaveChangesAsync();

    // Act
    var result = await TodoEndpointsV1.GetTodo(1, context);

    //Assert
    Assert.IsType<Results<Ok<Todo>, NotFound>>(result);

    var okResult = (Ok<Todo>)result.Result;

    Assert.NotNull(okResult.Value);
    Assert.Equal(1, okResult.Value.Id);
}
```

Middleware in Minimal API apps

Article • 07/26/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

WebApplication automatically adds the following middleware in Minimal API applications depending on certain conditions:

- UseDeveloperExceptionPage is added first when the HostingEnvironment is `"Development"`.
- UseRouting is added second if user code didn't already call `UseRouting` and if there are endpoints configured, for example `app.MapGet`.
- UseEndpoints is added at the end of the middleware pipeline if any endpoints are configured.
- UseAuthentication is added immediately after `UseRouting` if user code didn't already call `UseAuthentication` and if IAuthenticationSchemeProvider can be detected in the service provider. `IAuthenticationSchemeProvider` is added by default when using AddAuthentication, and services are detected using IServiceProviderIsService.
- UseAuthorization is added next if user code didn't already call `UseAuthorization` and if IAuthorizationHandlerProvider can be detected in the service provider. `IAuthorizationHandlerProvider` is added by default when using AddAuthorization, and services are detected using `IServiceProviderIsService`.
- User configured middleware and endpoints are added between `UseRouting` and `UseEndpoints`.

The following code is effectively what the automatic middleware being added to the app produces:

C#

```
if (isDevelopment)
{
    app.UseDeveloperExceptionPage();
}
```

```
app.UseRouting();

if (isAuthenticationConfigured)
{
    app.UseAuthentication();
}

if (isAuthorizationConfigured)
{
    app.UseAuthorization();
}

// user middleware/endpoints
app.CustomMiddleware(...);
app.MapGet("/", () => "hello world");
// end user middleware/endpoints

app.UseEndpoints(e => {});
```

In some cases, the default middleware configuration isn't correct for the app and requires modification. For example, UseCors should be called before UseAuthentication and UseAuthorization. The app needs to call `UseAuthentication` and `UseAuthorization` if `UseCors` is called:

C#

```
app.UseCors();
app.UseAuthentication();
app.UseAuthorization();
```

If middleware should be run before route matching occurs, UseRouting should be called and the middleware should be placed before the call to `UseRouting`. UseEndpoints isn't required in this case as it is automatically added as described previously:

C#

```
app.Use((context, next) =>
{
    return next(context);
});

app.UseRouting();

// other middleware and endpoints
```

When adding a terminal middleware:

- The middleware must be added after `UseEndpoints`.
- The app needs to call `UseRouting` and `UseEndpoints` so that the terminal middleware can be placed at the correct location.

C#

```
app.UseRouting();

app.MapGet("/", () => "hello world");

app.UseEndpoints(e => {});

app.Run(context =>
{
    context.Response.StatusCode = 404;
    return Task.CompletedTask;
});
```

Terminal middleware is middleware that runs if no endpoint handles the request.

How to handle errors in Minimal API apps

Article • 06/18/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the **.NET 8 version of this article**.

With contributions by David Acker

This article describes how to handle errors in Minimal API apps. For information about error handling in controller-based APIs, see Handle errors in ASP.NET Core and Handle errors in ASP.NET Core controller-based web APIs.

Exceptions

In a Minimal API app, there are two different built-in centralized mechanisms to handle unhandled exceptions:

- Developer Exception Page middleware (For use in the **Development environment only**.)
- Exception handler middleware

This section refers to the following sample app to demonstrate ways to handle exceptions in a Minimal API. It throws an exception when the endpoint `/exception` is requested:

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/exception", () =>
{
    throw new InvalidOperationException("Sample Exception");
});

app.MapGet("/", () => "Test by calling /exception");
```

```
app.Run();
```

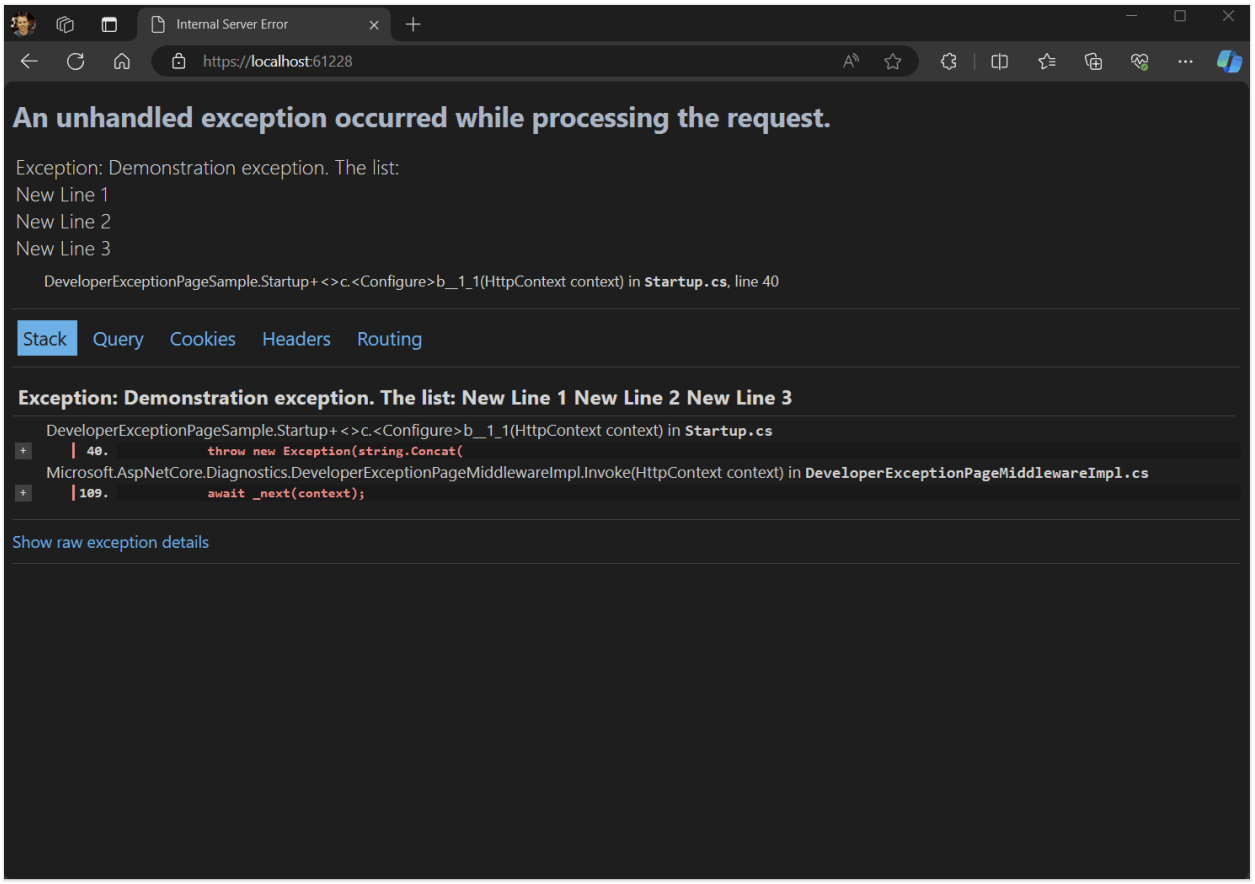
Developer Exception Page

The *Developer Exception Page* displays detailed information about unhandled request exceptions. It uses DeveloperExceptionPageMiddleware to capture synchronous and asynchronous exceptions from the HTTP pipeline and to generate error responses. The developer exception page runs early in the middleware pipeline, so that it can catch unhandled exceptions thrown in middleware that follows.

ASP.NET Core apps enable the developer exception page by default when both:

- Running in the Development environment.
- The app was created with the current templates, that is, by using WebApplication.CreateBuilder.

Apps created using earlier templates, that is, by using WebHost.CreateDefaultBuilder, can enable the developer exception page by calling app.UseDeveloperExceptionPage.



> ⚠ **Warning**
>
> Don't enable the Developer Exception Page **unless the app is running in the Development environment**. Don't share detailed exception information publicly when the app runs in production. For more information on configuring environments, see **Use multiple environments in ASP.NET Core**.

The Developer Exception Page can include the following information about the exception and the request:

- Stack trace
- Query string parameters, if any
- Cookies, if any
- Headers
- Endpoint metadata, if any

The Developer Exception Page isn't guaranteed to provide any information. Use Logging for complete error information.

The following image shows a sample developer exception page with animation to show the tabs and the information displayed:

In response to a request with an `Accept: text/plain` header, the Developer Exception Page returns plain text instead of HTML. For example:

text

```
Status: 500 Internal Server Error
Time: 9.39 msSize: 480 bytes
FormattedRawHeadersRequest
Body
text/plain; charset=utf-8, 480 bytes
System.InvalidOperationException: Sample Exception
   at WebApplicationMinimal.Program.<>c.<Main>b__0_0() in
C:\Source\WebApplicationMinimal\Program.cs:line 12
   at lambda_method1(Closure, Object, HttpContext)
   at
Microsoft.AspNetCore.Diagnostics.DeveloperExceptionPageMiddlewareImpl.Invoke
(HttpContext context)

HEADERS
=======
Accept: text/plain
Host: localhost:7267
traceparent: 00-0eab195ea19d07b90a46cd7d6bf2f
```

To see the Developer Exception Page:

- Run the sample app in the Development environment.
- Go to the `/exception` endpoint.

Exception handler

In non-development environments, use the Exception Handler Middleware to produce an error payload. To configure the `Exception Handler Middleware`, call UseExceptionHandler.

For example, the following code changes the app to respond with an RFC 7807 - compliant payload to the client. For more information, see the Problem Details section later in this article.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseExceptionHandler(exceptionHandlerApp
    => exceptionHandlerApp.Run(async context
        => await Results.Problem()
                      .ExecuteAsync(context)));

app.MapGet("/exception", () =>
{
    throw new InvalidOperationException("Sample Exception");
});

app.MapGet("/", () => "Test by calling /exception");

app.Run();
```

Client and Server error responses

Consider the following Minimal API app.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.MapGet("/users/{id:int}", (int id)
    => id <= 0 ? Results.BadRequest() : Results.Ok(new User(id)));

app.MapGet("/", () => "Test by calling /users/{id:int}");

app.Run();

public record User(int Id);
```

The `/users` endpoint produces `200 OK` with a `json` representation of `User` when `id` is greater than `0`, otherwise a `400 BAD REQUEST` status code without a response body. For more information about creating a response, see Create responses in Minimal API apps.

The Status Code Pages middleware can be configured to produce a common body content, **when empty**, for all HTTP client (`400`-`499`) or server (`500` -`599`) responses. The middleware is configured by calling the UseStatusCodePages extension method.

For example, the following example changes the app to respond with an RFC 7807 - compliant payload to the client for all client and server responses, including routing errors (for example, `404 NOT FOUND`). For more information, see the Problem Details section.

C#

```
var builder = WebApplication.CreateBuilder(args);
var app = builder.Build();

app.UseStatusCodePages(async statusCodeContext
    => await Results.Problem(statusCode:
statusCodeContext.HttpContext.Response.StatusCode)
                  .ExecuteAsync(statusCodeContext.HttpContext));
app.MapGet("/users/{id:int}", (int id)
    => id <= 0 ? Results.BadRequest() : Results.Ok(new User(id)) );

app.MapGet("/", () => "Test by calling /users/{id:int}");

app.Run();

public record User(int Id);
```

Problem details

Problem Details are not the only response format to describe an HTTP API error, however, they are commonly used to report errors for HTTP APIs.

The problem details service implements the IProblemDetailsService interface, which supports creating problem details in ASP.NET Core. The AddProblemDetails(IServiceCollection) extension method on IServiceCollection registers the default `IProblemDetailsService` implementation.

In ASP.NET Core apps, the following middleware generates problem details HTTP responses when `AddProblemDetails` is called, except when the Accept request HTTP header doesn't include one of the content types supported by the registered IProblemDetailsWriter (default: `application/json`):

- ExceptionHandlerMiddleware: Generates a problem details response when a custom handler is not defined.
- StatusCodePagesMiddleware: Generates a problem details response by default.
- DeveloperExceptionPageMiddleware: Generates a problem details response in development when the `Accept` request HTTP header doesn't include `text/html`.

Minimal API apps can be configured to generate problem details response for all HTTP client and server error responses that ***don't have body content yet*** by using the `AddProblemDetails` extension method.

The following code configures the app to generate problem details:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseExceptionHandler();
app.UseStatusCodePages();

app.MapGet("/users/{id:int}", (int id)
    => id <= 0 ? Results.BadRequest() : Results.Ok(new User(id)));

app.MapGet("/", () => "Test by calling /users/{id:int}");

app.Run();

public record User(int Id);
```

For more information on using `AddProblemDetails`, see Problem Details

IProblemDetailsService fallback

In the following code, `httpContext.Response.WriteAsync("Fallback: An error occurred.")` returns an error if the IProblemDetailsService implementation isn't able to generate a ProblemDetails:

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseExceptionHandler(exceptionHandlerApp =>
```

```
{
    exceptionHandlerApp.Run(async httpContext =>
    {
        var pds =
httpContext.RequestServices.GetService<IProblemDetailsService>();
        if (pds == null
            || !await pds.TryWriteAsync(new() { HttpContext = httpContext
}))
        {
            // Fallback behavior
            await httpContext.Response.WriteAsync("Fallback: An error
occurred.");
        }
    });
});

app.MapGet("/exception", () =>
{
    throw new InvalidOperationException("Sample Exception");
});

app.MapGet("/", () => "Test by calling /exception");

app.Run();
```

The preceding code:

- Writes an error message with the fallback code if the `problemDetailsService` is unable to write a `ProblemDetails`. For example, an endpoint where the Accept request header specifies a media type that the `DefaulProblemDetailsWriter` does not support.
- Uses the Exception Handler Middleware.

The following sample is similar to the preceding except that it calls the Status Code Pages middleware.

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddProblemDetails();

var app = builder.Build();

app.UseStatusCodePages(statusCodeHandlerApp =>
{
    statusCodeHandlerApp.Run(async httpContext =>
    {
        var pds =
httpContext.RequestServices.GetService<IProblemDetailsService>();
        if (pds == null
            || !await pds.TryWriteAsync(new() { HttpContext = httpContext
```

```
}))
        {
            // Fallback behavior
            await httpContext.Response.WriteAsync("Fallback: An error
occurred.");
        }
    });
});

app.MapGet("/users/{id:int}", (int id) =>
{
    return id <= 0 ? Results.BadRequest() : Results.Ok(new User(id));
});

app.MapGet("/", () => "Test by calling /users/{id:int}");

app.Run();

public record User(int Id);
```

Authentication and authorization in minimal APIs

Article • 07/26/2024

> **Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

Minimal APIs support all the authentication and authorization options available in ASP.NET Core and provide some additional functionality to improve the experience working with authentication.

Key concepts in authentication and authorization

Authentication is the process of determining a user's identity. Authorization is the process of determining whether a user has access to a resource. Both authentication and authorization scenarios share similar implementation semantics in ASP.NET Core. Authentication is handled by the authentication service, IAuthenticationService, which is used by authentication middleware. Authorization is handled by the authorization service, IAuthorizationService, which is used by the authorization middleware.

The authentication service uses registered authentication handlers to complete authentication-related actions. For example, an authentication-related action is authenticating a user or signing out a user. Authentication schemes are names that are used to uniquely identify an authentication handler and its configuration options. Authentication handlers are responsible for implementing the strategies for authentication and generating a user's claims given a particular authentication strategy, such as OAuth or OIDC. The configuration options are unique to the strategy as well and provide the handler with configuration that affects authentication behavior, such as redirect URIs.

There are two strategies for determining user access to resources in the authorization layer:

- Role-based strategies determine a user's access based on the role they are assigned, such as `Administrator` or `User`. For more information on role-based authorization, see role-based authorization documentation.
- Claim-based strategies determine a user's access based on claims that are issued by a central authority. For more information on claim-based authorization, see claim-based authorization documentation.

In ASP.NET Core, both strategies are captured into an authorization requirement. The authorization service leverages authorization handlers to determine whether or not a particular user meets the authorization requirements applied onto a resource.

Enabling authentication in minimal apps

To enable authentication, call AddAuthentication to register the required authentication services on the app's service provider.

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddAuthentication();
var app = builder.Build();

app.MapGet("/", () => "Hello World!");
app.Run();
```

Typically, a specific authentication strategy is used. In the following sample, the app is configured with support for JWT bearer-based authentication. This example makes use of the APIs available in the Microsoft.AspNetCore.Authentication.JwtBearer NuGet package.

C#

```
var builder = WebApplication.CreateBuilder(args);
// Requires Microsoft.AspNetCore.Authentication.JwtBearer
builder.Services.AddAuthentication().AddJwtBearer();
var app = builder.Build();

app.MapGet("/", () => "Hello World!");
app.Run();
```

By default, the WebApplication automatically registers the authentication and authorization middlewares if certain authentication and authorization services are enabled. In the following sample, it's not necessary to invoke UseAuthentication or

UseAuthorization to register the middlewares because WebApplication does this automatically after `AddAuthentication` or `AddAuthorization` are called.

C#

```
var builder = WebApplication.CreateBuilder(args);
builder.Services.AddAuthentication().AddJwtBearer();
builder.Services.AddAuthorization();
var app = builder.Build();

app.MapGet("/", () => "Hello World!");
app.Run();
```

In some cases, such as controlling middleware order, it's necessary to explicitly register authentication and authorization. In the following sample, the authentication middleware runs *after* the CORS middleware has run. For more information on middlewares and this automatic behavior, see Middleware in Minimal API apps.

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddCors();
builder.Services.AddAuthentication().AddJwtBearer();
builder.Services.AddAuthorization();

var app = builder.Build();

app.UseCors();
app.UseAuthentication();
app.UseAuthorization();

app.MapGet("/", () => "Hello World!");
app.Run();
```

Configuring authentication strategy

Authentication strategies typically support a variety of configurations that are loaded via options. Minimal apps support loading options from configuration for the following authentication strategies:

- JWT bearer-based
- OpenID Connection-based

The ASP.NET Core framework expects to find these options under the `Authentication:Schemes:{SchemeName}` section in configuration. In the following sample,

two different schemes, `Bearer` and `LocalAuthIssuer`, are defined with their respective options. The `Authentication:DefaultScheme` option can be used to configure the default authentication strategy that's used.

JSON

```
{
  "Authentication": {
    "DefaultScheme":  "LocalAuthIssuer",
    "Schemes": {
      "Bearer": {
        "ValidAudiences": [
          "https://localhost:7259",
          "http://localhost:5259"
        ],
        "ValidIssuer": "dotnet-user-jwts"
      },
      "LocalAuthIssuer": {
        "ValidAudiences": [
          "https://localhost:7259",
          "http://localhost:5259"
        ],
        "ValidIssuer": "local-auth"
      }
    }
  }
}
```

In `Program.cs`, two JWT bearer-based authentication strategies are registered, with the:

- "Bearer" scheme name.
- "LocalAuthIssuer" scheme name.

"Bearer" is the typical default scheme in JWT-bearer based enabled apps, but the default scheme can be overridden by setting the `DefaultScheme` property as in the preceding example.

The scheme name is used to uniquely identify an authentication strategy and is used as the lookup key when resolving authentication options from config, as shown in the following example:

C#

```
var builder = WebApplication.CreateBuilder(args);

builder.Services.AddAuthentication()
  .AddJwtBearer()
  .AddJwtBearer("LocalAuthIssuer");
```

```
var app = builder.Build();

app.MapGet("/", () => "Hello World!");
app.Run();
```

Configuring authorization policies in minimal apps

Authentication is used to identify and validate the identity of users against an API. Authorization is used to validate and verify access to resources in an API and is facilitated by the `IAuthorizationService` registered by the `AddAuthorization` extension method. In the following scenario, a `/hello` resource is added that requires a user to present an `admin` role claim with a `greetings_api` scope claim.

Configuring authorization requirements on a resource is a two-step process that requires:

1. Configuring the authorization requirements in a policy globally.
2. Applying individual policies to resources.

In the following code, AddAuthorizationBuilder is invoked which:

- Adds authorization-related services to the DI container.
- Returns an AuthorizationBuilder that can be used to directly register authorization policies.

The code creates a new authorization policy, named `admin_greetings`, that encapsulates two authorization requirements:

- A role-based requirement via RequireRole for users with an `admin` role.
- A claim-based requirement via RequireClaim that the user must provide a `greetings_api` scope claim.

The `admin_greetings` policy is provided as a required policy to the `/hello` endpoint.

C#

```
using Microsoft.Identity.Web;

var builder = WebApplication.CreateBuilder(args);
```

```
builder.Services.AddAuthorizationBuilder()
  .AddPolicy("admin_greetings", policy =>
        policy
            .RequireRole("admin")
            .RequireClaim("scope", "greetings_api"));

var app = builder.Build();

app.MapGet("/hello", () => "Hello world!")
  .RequireAuthorization("admin_greetings");

app.Run();
```

Use `dotnet user-jwts` for development testing

Throughout this article, an app configured with JWT-bearer based authentication is used. JWT bearer-based authentication requires that clients present a token in the request header to validate their identity and claims. Typically, these tokens are issued by a central authority, such as an identity server.

When developing on the local machine, the dotnet user-jwts tool can be used to create bearer tokens.

.NET CLI

```
dotnet user-jwts create
```

> **Note**
>
> When invoked on a project, the tool automatically adds the authentication options matching the generated token to `appsettings.json`.

Tokens can be configured with a variety of customizations. For example, to create a token for the `admin` role and `greetings_api` scope expected by the authorization policy in the preceding code:

.NET CLI

```
dotnet user-jwts create --scope "greetings_api" --role "admin"
```

The generated token can then be sent as part of the header in the testing tool of choice. For example, with curl:

```
```

.NET CLI

```
curl -i -H "Authorization: Bearer {token}" https://localhost:{port}/hello
```

For more information on the `dotnet user-jwts` tool, read the complete documentation.

OpenAPI support in ASP.NET Core API apps

Article • 10/28/2024

> **ⓘ Important**
>
> This information relates to a pre-release product that may be substantially modified before it's commercially released. Microsoft makes no warranties, express or implied, with respect to the information provided here.
>
> For the current release, see the .NET 8 version of this article.

ASP.NET Core supports the generation of OpenAPI documents in controller-based and minimal APIs apps. The OpenAPI specification is a programming language-agnostic standard for documenting HTTP APIs. This standard is supported in ASP.NET Core apps through a combination of built-in APIs and open-source libraries. There are three key aspects to OpenAPI integration in an application:

- Generating information about the endpoints in the app.
- Gathering the information into a format that matches the OpenAPI schema.
- Exposing the generated OpenAPI document via a visual UI or a serialized file.

ASP.NET Core apps provide built-in support for generating information about endpoints in an app via the `Microsoft.AspNetCore.OpenApi` package.

The following code is generated by the ASP.NET Core minimal web API template and uses OpenAPI:

C#

```
using Microsoft.AspNetCore.OpenApi;

var builder = WebApplication.CreateBuilder(args);

builder.Services.AddOpenApi();

var app = builder.Build();

if (app.Environment.IsDevelopment())
{
    app.MapOpenApi();
}

app.UseHttpsRedirection();
```

```
var summaries = new[]
{
    "Freezing", "Bracing", "Chilly", "Cool", "Mild", "Warm", "Balmy", "Hot",
"Sweltering", "Scorching"
};

app.MapGet("/weatherforecast", () =>
{
    var forecast = Enumerable.Range(1, 5).Select(index =>
        new WeatherForecast
        (
            DateTime.Now.AddDays(index),
            Random.Shared.Next(-20, 55),
            summaries[Random.Shared.Next(summaries.Length)]
        ))
        .ToArray();
    return forecast;
})
.WithName("GetWeatherForecast");

app.Run();

internal record WeatherForecast(DateTime Date, int TemperatureC, string?
Summary)
{
    public int TemperatureF => 32 + (int)(TemperatureC / 0.5556);
}
```

In the preceding highlighted code:

- `AddOpenApi` registers services required for OpenAPI document generation into the application's DI container.
- `MapOpenApi` adds an endpoint into the application for viewing the OpenAPI document serialized into JSON. The OpenAPI endpoint is restricted to the development environment to minimize the risk of exposing sensitive information and reduce the vulnerabilities in production.

`Microsoft.AspNetCore.OpenApi` NuGet package

The Microsoft.AspNetCore.OpenApi package provides the following features:

- Support for generating OpenAPI documents at run time and accessing them via an endpoint on the application.
- Support for "transformer" APIs that allow modifying the generated document.

To use the `Microsoft.AspNetCore.OpenApi` package, add it as a PackageReference to a project file:

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net9.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
  </PropertyGroup>

  <PropertyGroup>
    <OpenApiGenerateDocuments>true</OpenApiGenerateDocuments>
    <OpenApiDocumentsDirectory>$(MSBuildProjectDirectory)
</OpenApiDocumentsDirectory>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.OpenApi" Version="9.0.*-
*" />
    <PackageReference Include="Microsoft.Extensions.ApiDescription.Server"
Version="9.0.*-*">
      <IncludeAssets>runtime; build; native; contentfiles; analyzers;
buildtransitive</IncludeAssets>
      <PrivateAssets>all</PrivateAssets>
    </PackageReference>
  </ItemGroup>

</Project>
```

To learn more about the `Microsoft.AspNetCore.OpenApi` package, see Generate OpenAPI documents.

`Microsoft.Extensions.ApiDescription.Server` NuGet package

The Microsoft.Extensions.ApiDescription.Server package provides support for generating OpenAPI documents at build time and serializing them.

To use `Microsoft.Extensions.ApiDescription.Server`, add it as a PackageReference to a project file. Document generation at build time is enabled by setting the `OpenApiGenerateDocuments` property. By default, the generated OpenAPI document is saved to the `obj` directory, but you can customize the output directory by setting the `OpenApiDocumentsDirectory` property.

XML

```
<Project Sdk="Microsoft.NET.Sdk.Web">

  <PropertyGroup>
    <TargetFramework>net9.0</TargetFramework>
    <Nullable>enable</Nullable>
    <ImplicitUsings>enable</ImplicitUsings>
  </PropertyGroup>

  <PropertyGroup>
    <OpenApiGenerateDocuments>true</OpenApiGenerateDocuments>
    <OpenApiDocumentsDirectory>$(MSBuildProjectDirectory)
</OpenApiDocumentsDirectory>
  </PropertyGroup>

  <ItemGroup>
    <PackageReference Include="Microsoft.AspNetCore.OpenApi" Version="9.0.*-
*" />
    <PackageReference Include="Microsoft.Extensions.ApiDescription.Server"
Version="9.0.*-*">
      <IncludeAssets>runtime; build; native; contentfiles; analyzers;
buildtransitive</IncludeAssets>
      <PrivateAssets>all</PrivateAssets>
    </PackageReference>
  </ItemGroup>

</Project>
```

Generate OpenAPI documents

Article • 11/04/2024

The Microsoft.AspNetCore.OpenApi package provides built-in support for OpenAPI document generation in ASP.NET Core. The package provides the following features:

- Support for generating OpenAPI documents at run time and accessing them via an endpoint on the application.
- Support for "transformer" APIs that allow modifying the generated document.
- Support for generating multiple OpenAPI documents from a single app.
- Takes advantage of JSON schema support provided by System.Text.Json.
- Is compatible with native AoT.

Package installation

Install the `Microsoft.AspNetCore.OpenApi` package:

Visual Studio

Run the following command from the **Package Manager Console**:

PowerShell

```
Install-Package Microsoft.AspNetCore.OpenApi -IncludePrerelease
```

Configure OpenAPI document generation

The following code:

- Adds OpenAPI services.
- Enables the endpoint for viewing the OpenAPI document in JSON format.

C#

```
var builder = WebApplication.CreateBuilder();

builder.Services.AddOpenApi();

var app = builder.Build();

app.MapOpenApi();
```

```
app.MapGet("/", () => "Hello world!");

app.Run();
```

Launch the app and navigate to `https://localhost:<port>/openapi/v1.json` to view the generated OpenAPI document.

Options to Customize OpenAPI document generation

The following sections demonstrate how to customize OpenAPI document generation.

Customize the OpenAPI document name

Each OpenAPI document in an app has a unique name. The default document name that is registered is `v1`.

C#

```
builder.Services.AddOpenApi(); // Document name is v1
```

The document name can be modified by passing the name as a parameter to the `AddOpenApi` call.

C#

```
builder.Services.AddOpenApi("internal"); // Document name is internal
```

The document name surfaces in several places in the OpenAPI implementation.

When fetching the generated OpenAPI document, the document name is provided as the `documentName` parameter argument in the request. The following requests resolve the `v1` and `internal` documents.

Bash

```
GET http://localhost:5000/openapi/v1.json
GET http://localhost:5000/openapi/internal.json
```

Customize the OpenAPI version of a generated document

By default, OpenAPI document generation creates a document that is compliant with v3.0 of the OpenAPI specification. The following code demonstrates how to modify the default version of the OpenAPI document:

```
C#

builder.Services.AddOpenApi(options =>
{
    options.OpenApiVersion = OpenApiSpecVersion.OpenApi2_0;
});
```

Customize the OpenAPI endpoint route

By default, the OpenAPI endpoint registered via a call to MapOpenApi exposes the document at the `/openapi/{documentName}.json` endpoint. The following code demonstrates how to customize the route at which the OpenAPI document is registered:

```
C#

app.MapOpenApi("/openapi/{documentName}/openapi.json");
```

It's possible, but not recommended, to remove the `documentName` route parameter from the endpoint route. When the `documentName` route parameter is removed from the endpoint route, the framework attempts to resolve the document name from the query parameter. Not providing the `documentName` in either the route or query can result in unexpected behavior.

Customize the OpenAPI endpoint

Because the OpenAPI document is served via a route handler endpoint, any customization that is available to standard minimal endpoints is available to the OpenAPI endpoint.

Limit OpenAPI document access to authorized users

The OpenAPI endpoint doesn't enable any authorization checks by default. However, authorization checks can be applied to the OpenAPI document. In the following code, access to the OpenAPI document is limited to those with the `tester` role:

```
C#
```

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.OpenApi;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.OpenApi.Models;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAuthentication().AddJwtBearer();
builder.Services.AddAuthorization(o =>
{
    o.AddPolicy("ApiTesterPolicy", b => b.RequireRole("tester"));
});
builder.Services.AddOpenApi();

var app = builder.Build();

app.MapOpenApi()
    .RequireAuthorization("ApiTesterPolicy");

app.MapGet("/", () => "Hello world!");

app.Run();
```

Cache generated OpenAPI document

The OpenAPI document is regenerated every time a request to the OpenAPI endpoint is sent. Regeneration enables transformers to incorporate dynamic application state into their operation. For example, regenerating a request with details of the HTTP context. When applicable, the OpenAPI document can be cached to avoid executing the document generation pipeline on each HTTP request.

C#

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.OpenApi;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.OpenApi.Models;

var builder = WebApplication.CreateBuilder();

builder.Services.AddOutputCache(options =>
{
    options.AddBasePolicy(policy =>
policy.Expire(TimeSpan.FromMinutes(10)));
});
builder.Services.AddOpenApi();

var app = builder.Build();
```

```
app.UseOutputCache();

app.MapOpenApi()
    .CacheOutput();

app.MapGet("/", () => "Hello world!");

app.Run();
```

Generate OpenAPI documents at build-time

In typical web applications, OpenAPI documents are generated at run-time and served via an HTTP request to the application server.

In some scenarios, it's helpful to generate the OpenAPI document during the application's build step. These scenarios include:

- Generating OpenAPI documentation that is committed into source control.
- Generating OpenAPI documentation that is used for spec-based integration testing.
- Generating OpenAPI documentation that is served statically from the web server.

To add support for generating OpenAPI documents at build time, install the `Microsoft.Extensions.ApiDescription.Server` package:

Visual Studio

Run the following command from the **Package Manager Console**:

PowerShell

```
Install-Package Microsoft.Extensions.ApiDescription.Server -
IncludePrerelease
```

Upon installation, this package will automatically generate the Open API document(s) associated with the application during build and populate them into the application's output directory.

cli

```
$ dotnet build
$ cat bin/Debug/net9.0/{ProjectName}.json
```

Customizing build-time document generation

Modifying the output directory of the generated Open API file

By default, the generated OpenAPI document will be emitted to the application's output directory. To modify the location of the emitted file, set the target path in the `OpenApiDocumentsDirectory` property.

XML

```
<PropertyGroup>
  <OpenApiDocumentsDirectory>./</OpenApiDocumentsDirectory>
</PropertyGroup>
```

The value of `OpenApiDocumentsDirectory` is resolved relative to the project file. Using the `./` value above will emit the OpenAPI document in the same directory as the project file.

Modifying the output file name

By default, the generated OpenAPI document will have the same name as the application's project file. To modify the name of the emitted file, set the `--file-name` argument in the `OpenApiGenerateDocumentsOptions` property.

XML

```
<PropertyGroup>
  <OpenApiGenerateDocumentsOptions>--file-name my-open-
api</OpenApiGenerateDocumentsOptions>
</PropertyGroup>
```

Selecting the OpenAPI document to generate

Some applications may be configured to emit multiple OpenAPI documents, for various versions of an API or to distinguish between public and internal APIs. By default, the build-time document generator will emit files for all documents that are configured in an application. To only emit for a single document name, set the `--document-name` argument in the `OpenApiGenerateDocumentsOptions` property.

XML

```
<PropertyGroup>
  <OpenApiGenerateDocumentsOptions>--document-name
v2</OpenApiGenerateDocumentsOptions>
</PropertyGroup>
```

Customizing run-time behavior during build-time document generation

Under the hood, build-time OpenAPI document generation functions by launching the application's entrypoint with an inert server implementation. This is a requirement to produce accurate OpenAPI documents since all information in the OpenAPI document cannot be statically analyzed. Because the application's entrypoint is invoked, any logic in the applications' startup will be invoked. This includes code that injects services into the DI container or reads from configuration. In some scenarios, it's necessary to restrict the codepaths that will run when the application's entry point is being invoked from build-time document generation. These scenarios include:

- Not reading from certain configuration strings.
- Not registering database-related services.

In order to restrict these codepaths from being invoked by the build-time generation pipeline, they can be conditioned behind a check of the entry assembly like so:

C#

```
using System.Reflection;

var builder = WebApplication.CreateBuilder();

if (Assembly.GetEntryAssembly()?.GetName().Name != "GetDocument.Insider")
{
  builder.Services.AddDefaults();
}
```

Include OpenAPI metadata in an ASP.NET Core app

Article • 11/06/2024

Include OpenAPI metadata for endpoints

ASP.NET collects metadata from the web app's endpoints and uses it to generate an OpenAPI document. In controller-based apps, metadata is collected from attributes like [EndpointDescription], [HttpPost], and [Produces]. In minimal APIs, metadata can be collected from attributes, but may also be set by using extension methods and other strategies, such as returning TypedResults from route handlers. The following table provides an overview of the metadata collected and the strategies for setting it.

Expand table

Metadata	Attribute	Extension method	Other strategies
summary	[EndpointSummary]	WithSummary	
description	[EndpointDescription]	WithDescription	
tags	[Tags]	WithTags	
operationId	[EndpointName]	WithName	
parameters	[FromQuery], [FromRoute], [FromHeader], [FromForm]		
parameter description	[EndpointDescription]		
requestBody	[FromBody]	Accepts	
responses	[Produces]	Produces, ProducesProblem	TypedResults
Excluding endpoints	[ExcludeFromDescription], [ApiExplorerSettings]	ExcludeFromDescription	

ASP.NET Core does not collect metadata from XML doc comments.

The following sections demonstrate how to include metadata in an app to customize the generated OpenAPI document.

Summary and description

The endpoint summary and description can be set using the [EndpointSummary] and [EndpointDescription] attributes, or in minimal APIs, using the WithSummary and WithDescription extension methods.

Minimal APIs

The following sample demonstrates the different strategies for setting summaries and descriptions.

Note that the attributes are placed on the delegate method and not on the app.MapGet method.

C#

```
app.MapGet("/extension-methods", () => "Hello world!")
  .WithSummary("This is a summary.")
  .WithDescription("This is a description.");

app.MapGet("/attributes",
  [EndpointSummary("This is a summary.")]
  [EndpointDescription("This is a description.")]
  () => "Hello world!");
```

tags

OpenAPI supports specifying tags on each endpoint as a form of categorization.

Minimal APIs

In minimal APIs, tags can be set using either the [Tags] attribute or the WithTags extension method.

The following sample demonstrates the different strategies for setting tags.

C#

```
app.MapGet("/extension-methods", () => "Hello world!")
  .WithTags("todos", "projects");

app.MapGet("/attributes",
```

```
  [Tags("todos", "projects")]
  () => "Hello world!");
```

operationId

OpenAPI supports an operationId on each endpoint as a unique identifier or name for the operation.

Minimal APIs

In minimal APIs, the operationId can be set using either the [EndpointName] attribute or the WithName extension method.

The following sample demonstrates the different strategies for setting the operationId.

C#

```
app.MapGet("/extension-methods", () => "Hello world!")
  .WithName("FromExtensionMethods");

app.MapGet("/attributes",
  [EndpointName("FromAttributes")]
  () => "Hello world!");
```

parameters

OpenAPI supports annotating path, query string, header, and cookie parameters that are consumed by an API.

The framework infers the types for request parameters automatically based on the signature of the route handler.

The [EndpointDescription] attribute can be used to provide a description for a parameter.

Minimal APIs

The follow sample demonstrates how to set a description for a parameter.

C#

```
app.MapGet("/attributes",
  ([Description("This is a description.")] string name) => "Hello
world!");
```

Describe the request body

The `requestBody` field in OpenAPI describes the body of a request that an API client can send to the server, including the content type(s) supported and the schema for the body content.

When the endpoint handler method accepts parameters that are bound from the request body, ASP.NET Core generates a corresponding `requestBody` for the operation in the OpenAPI document. Metadata for the request body can also be specified using attributes or extension methods. Additional metadata can be set with a document transformer or operation transformer.

If the endpoint doesn't define any parameters bound to the request body, but instead consumes the request body from the HttpContext directly, ASP.NET Core provides mechanisms to specify request body metadata. This is a common scenario for endpoints that process the request body as a stream.

Some request body metadata can be determined from the FromBody or FromForm parameters of the route handler method.

A description for the request body can be set with a [Description] attribute on the parameter with FromBody or FromForm.

If the FromBody parameter is non-nullable and EmptyBodyBehavior is not set to Allow in the FromBody attribute, the request body is required and the `required` field of the `requestBody` is set to `true` in the generated OpenAPI document. Form bodies are always required and have `required` set to `true`.

Use a document transformer or an operation transformer to set the `example`, `examples`, or `encoding` fields, or to add specification extensions for the request body in the generated OpenAPI document.

Other mechanisms for setting request body metadata depend on the type of app being developed and are described in the following sections.

Minimal APIs

The content types for the request body in the generated OpenAPI document are determined from the type of the parameter that is bound to the request body or specified with the Accepts extension method. By default, the content type of a FromBody parameter will be `application/json` and the content type for FromForm parameter(s) will be `multipart/form-data` or `application/x-www-form-urlencoded`.

Support for these default content types is built in to Minimal APIs, and other content types can be handled by using custom binding. See the Custom binding topic of the Minimal APIs documentation for more information.

There are several ways to specify a different content type for the request body. If the type of the FromBody parameter implements IEndpointParameterMetadataProvider, ASP.NET Core uses this interface to determine the content type(s) in the request body. The framework uses the PopulateMetadata method of this interface to set the content type(s) and type of the body content of the request body. For example, a `Todo` class that accepts either `application/xml` or `text/xml` content-type can use IEndpointParameterMetadataProvider to provide this information to the framework.

C#

```
public class Todo : IEndpointParameterMetadataProvider
{
    public static void PopulateMetadata(ParameterInfo parameter,
EndpointBuilder builder)
    {
        builder.Metadata.Add(new AcceptsMetadata(["application/xml",
"text/xml"], typeof(Todo)));
    }
}
```

The Accepts extension method can also be used to specify the content type of the request body. In the following example, the endpoint accepts a `Todo` object in the request body with an expected content-type of `application/xml`.

C#

```
app.MapPut("/todos/{id}", (int id, Todo todo) => ...)
  .Accepts<Todo>("application/xml");
```

Since `application/xml` is not a built-in content type, the `Todo` class must implement the IBindableFromHttpContext<TSelf> interface to provide a custom binding for the request body. For example:

C#

```
public class Todo : IBindableFromHttpContext<Todo>
{
    public static async ValueTask<Todo?> BindAsync(HttpContext context,
ParameterInfo parameter)
    {
        var xmlDoc = await XDocument.LoadAsync(context.Request.Body,
LoadOptions.None, context.RequestAborted);
        var serializer = new XmlSerializer(typeof(Todo));
        return (Todo?)serializer.Deserialize(xmlDoc.CreateReader());
    }
```

If the endpoint doesn't define any parameters bound to the request body, use the Accepts extension method to specify the content type that the endpoint accepts.

If you specify <AspNetCore.Http.OpenApiRouteHandlerBuilderExtensions.Accepts%2A> multiple times, only metadata from the last one is used -- they aren't combined.

Describe response types

OpenAPI supports providing a description of the responses returned from an API. ASP.NET Core provides several strategies for setting the response metadata of an endpoint. Response metadata that can be set includes the status code, the type of the response body, and content type(s) of a response. Responses in OpenAPI may have additional metadata, such as description, headers, links, and examples. This additional metadata can be set with a document transformer or operation transformer.

The specific mechanisms for setting response metadata depend on the type of app being developed.

Minimal APIs

In Minimal API apps, ASP.NET Core can extract the response metadata added by extension methods on the endpoint, attributes on the route handler, and the return type of the route handler.

- The Produces extension method can be used on the endpoint to specify the status code, the type of the response body, and content type(s) of a response from an endpoint.
- The [ProducesResponseType] or ProducesResponseTypeAttribute<T> attribute can be used to specify the type of the response body.

- A route handler can be used to return a type that implements IEndpointMetadataProvider to specify the type and content-type(s) of the response body.
- The ProducesProblem extension method on the endpoint can be used to specify the status code and content-type(s) of an error response.

Note that the Produces and ProducesProblem extension methods are supported on both RouteHandlerBuilder and on RouteGroupBuilder. This allows, for example, a common set of error responses to be defined for all operations in a group.

When not specified by one of the preceding strategies, the:

- Status code for the response defaults to 200.
- Schema for the response body can be inferred from the implicit or explicit return type of the endpoint method, for example, from `T` in Task<TResult>; otherwise, it's considered to be unspecified.
- Content-type for the specified or inferred response body is "application/json".

In Minimal APIs, the Produces extension method and the [ProducesResponseType] attribute only set the response metadata for the endpoint. They do not modify or constrain the behavior of the endpoint, which may return a different status code or response body type than specified by the metadata, and the content-type is determined by the return type of the route handler method, irrespective of any content-type specified in attributes or extension methods.

The Produces extension method can specify an endpoint's response type, with a default status code of 200 and a default content type of `application/json`. The following example illustrates this:

C#

```
app.MapGet("/todos", async (TodoDb db) => await db.Todos.ToListAsync())
  .Produces<IList<Todo>>();
```

The [ProducesResponseType] can be used to add response metadata to an endpoint. Note that the attribute is applied to the route handler method, not the method invocation to create the route, as shown in the following example:

C#

```
app.MapGet("/todos",
    [ProducesResponseType<List<Todo>>(200)]
    async (TodoDb db) => await db.Todos.ToListAsync());
```

Using TypedResults in the implementation of an endpoint's route handler automatically includes the response type metadata for the endpoint. For example, the following code automatically annotates the endpoint with a response under the `200` status code with an `application/json` content type.

C#

```
app.MapGet("/todos", async (TodoDb db) =>
{
    var todos = await db.Todos.ToListAsync();
    return TypedResults.Ok(todos);
});
```

Only return types that implement IEndpointMetadataProvider create a `responses` entry in the OpenAPI document. The following is a partial list of some of the TypedResults helper methods that produce a `responses` entry:

Expand table

TypedResults helper method	status code
Ok()	200
Created()	201
CreatedAtRoute()	201
Accepted()	202
AcceptedAtRoute()	202
NoContent()	204
BadRequest()	400
ValidationProblem()	400
NotFound()	404
Conflict()	409
UnprocessableEntity()	422

All of these methods except `NoContent` have a generic overload that specifies the type of the response body.

A class can be implemented to set the endpoint metadata and return it from the route handler.

Set responses for `ProblemDetails`

When setting the response type for endpoints that may return a ProblemDetails response, the following can be used to add the appropriate response metadata for the endpoint:

- ProducesProblem
- ProducesValidationProblem extension method.
- TypedResults with a status code in the (400-499) range.

For more information on how to configure a Minimal API app to return ProblemDetails responses, see Handle errors in minimal APIs.

Multiple response types

If an endpoint can return different response types in different scenarios, you can provide metadata in the following ways:

- Call the Produces extension method multiple times, as shown in the following example:

```
C#
```

```
app.MapGet("/api/todoitems/{id}", async (int id, TodoDb db) =>
        await db.Todos.FindAsync(id)
        is Todo todo
        ? Results.Ok(todo)
        : Results.NotFound())
   .Produces<Todo>(StatusCodes.Status200OK)
   .Produces(StatusCodes.Status404NotFound);
```

- Use Results<TResult1,TResult2,TResult3,TResult4,TResult5,TResult6> in the signature and TypedResults in the body of the handler, as shown in the following example:

```
C#
```

```
app.MapGet("/book/{id}", Results<Ok<Book>, NotFound> (int id,
List<Book> bookList) =>
{
    return bookList.FirstOrDefault((i) => i.Id == id) is Book book
     ? TypedResults.Ok(book)
     : TypedResults.NotFound();
});
```

The `Results<TResult1,TResult2,TResultN>` union types declare that a route handler returns multiple `IResult`-implementing concrete types, and any of those types that implement IEndpointMetadataProvider will contribute to the endpoint's metadata.

The union types implement implicit cast operators. These operators enable the compiler to automatically convert the types specified in the generic arguments to an instance of the union type. This capability has the added benefit of providing compile-time checking that a route handler only returns the results that it declares it does. Attempting to return a type that isn't declared as one of the generic arguments to `Results<TResult1,TResult2,TResultN>` results in a compilation error.

Exclude endpoints from the generated document

By default, all endpoints that are defined in an app are documented in the generated OpenAPI file, but endpoints can be excluded from the document using attributes or extension methods.

The mechanism for specifying an endpoint that should be excluded depends on the type of app being developed.

Minimal APIs

Minimal APIs support two strategies for excluding a given endpoint from the OpenAPI document:

- ExcludeFromDescription extension method
- [ExcludeFromDescription] attribute

The following sample demonstrates the different strategies for excluding a given endpoint from the generated OpenAPI document.

C#

```
app.MapGet("/extension-method", () => "Hello world!")
  .ExcludeFromDescription();

app.MapGet("/attributes",
  [ExcludeFromDescription]
  () => "Hello world!");
```

Include OpenAPI metadata for data types

C# classes or records used in request or response bodies are represented as schemas in the generated OpenAPI document. By default, only public properties are represented in the schema, but there are JsonSerializerOptions to also create schema properties for fields.

When the PropertyNamingPolicy is set to camel-case (this is the default in ASP.NET web applications), property names in a schema are the camel-case form of the class or record property name. The [JsonPropertyName] can be used on an individual property to specify the name of the property in the schema.

type and format

The JSON Schema library maps standard C# types to OpenAPI `type` and `format` as follows:

Expand table

C# Type	OpenAPI `type`	OpenAPI `format`
int	integer	int32
long	integer	int64
short	integer	int16
byte	integer	uint8
float	number	float
double	number	double
decimal	number	double
bool	boolean	
string	string	
char	string	char
byte[]	string	byte
DateTimeOffset	string	date-time
DateOnly	string	date
TimeOnly	string	time

C# Type	OpenAPI `type`	OpenAPI `format`
Uri	string	uri
Guid	string	uuid
object	*omitted*	
dynamic	*omitted*	

Note that object and dynamic types have *no* type defined in the OpenAPI because these can contain data of any type, including primitive types like int or string.

The `type` and `format` can also be set with a Schema Transformer. For example, you may want the `format` of decimal types to be `decimal` instead of `double`.

Use attributes to add metadata

ASP.NET uses metadata from attributes on class or record properties to set metadata on the corresponding properties of the generated schema.

The following table summarizes attributes from the `System.ComponentModel` namespace that provide metadata for the generated schema:

Expand table

Attribute	Description
[Description]	Sets the `description` of a property in the schema.
[Required]	Marks a property as `required` in the schema.
[DefaultValue]	Sets the `default` value of a property in the schema.
[Range]	Sets the `minimum` and `maximum` value of an integer or number.
[MinLength]	Sets the `minLength` of a string.
[MaxLength]	Sets the `maxLength` of a string.
[RegularExpression]	Sets the `pattern` of a string.

Note that in controller-based apps, these attributes add filters to the operation to validate that any incoming data satisfies the constraints. In Minimal APIs, these attributes set the metadata in the generated schema but validation must be performed explicitly via an endpoint filter, in the route handler's logic, or via a third-party package.

Attributes can also be placed on parameters in the parameter list of a record definition but must include the `property` modifier. For example:

C#

```
public record Todo(
    [property: Required]
    [property: Description("The unique identifier for the todo")]
    int Id,
    [property: Description("The title of the todo")]
    [property: MaxLength(120)]
    string Title,
    [property: Description("Whether the todo has been completed")]
    bool Completed
) {}
```

Other sources of metadata for generated schemas

required

In a class, struct, or record, properties with the [Required] attribute or required modifier are always `required` in the corresponding schema.

Other properties may also be required based on the constructors (implicit and explicit) for the class, struct, or record.

- For a class or record class with a single public constructor, any property with the same type and name (case-insensitive match) as a parameter to the constructor is required in the corresponding schema.
- For a class or record class with multiple public constructors, no other properties are required.
- For a struct or record struct, no other properties are required since C# always defines an implicit parameterless constructor for a struct.

enum

Enum types in C# are integer-based, but can be represented as strings in JSON with a [JsonConverter] and a JsonStringEnumConverter. When an enum type is represented as a string in JSON, the generated schema will have an `enum` property with the string values of the enum.

The following example demonstrates how to use a `JsonStringEnumConverter` to represent an enum as a string in JSON:

C#

```
[JsonConverter(typeof(JsonStringEnumConverter<DayOfTheWeekAsString>))]
public enum DayOfTheWeekAsString
{
    Sunday,
    Monday,
    Tuesday,
    Wednesday,
    Thursday,
    Friday,
    Saturday
}
```

A special case is when an enum type has the [Flags] attribute, which indicates that the enum can be treated as a bit field; that is, a set of flags. A flags enum with a [JsonConverterAttribute] will be defined as `type: string` in the generated schema with no `enum` property, since the value could be any combination of the enum values. For example, the following enum:

C#

```
[Flags, JsonConverter(typeof(JsonStringEnumConverter<PizzaToppings>))]
public enum PizzaToppings { Pepperoni = 1, Sausage = 2, Mushrooms = 4,
Anchovies = 8 }
```

could have values such as `"Pepperoni, Sausage"` or `"Sausage, Mushrooms, Anchovies"`.

An enum type without a [JsonConverter] will be defined as `type: integer` in the generated schema.

Note: The [AllowedValues] attribute does not set the `enum` values of a property.

nullable

Properties defined as a nullable value or reference type have `nullable: true` in the generated schema. This is consistent with the default behavior of the System.Text.Json deserializer, which accepts `null` as a valid value for a nullable property.

additionalProperties

Schemas are generated without an `additionalProperties` assertion by default, which implies the default of `true`. This is consistent with the default behavior of the

System.Text.Json deserializer, which silently ignores additional properties in a JSON object.

If the additional properties of a schema should only have values of a specific type, define the property or class as a `Dictionary<string, type>`. The key type for the dictionary must be `string`. This generates a schema with `additionalProperties` specifying the schema for "type" as the required value types.

Polymorphic types

Use the [JsonPolymorphic] and [JsonDerivedType] attributes on a parent class to to specify the discriminator field and subtypes for a polymorphic type.

The [JsonDerivedType] adds the discriminator field to the schema for each subclass, with an enum specifying the specific discriminator value for the subclass. This attribute also modifies the constructor of each derived class to set the discriminator value.

An abstract class with a [JsonPolymorphic] attribute has a `discriminator` field in the schema, but a concrete class with a [JsonPolymorphic] attribute doesn't have a `discriminator` field. OpenAPI requires that the discriminator property be a required property in the schema, but since the discriminator property isn't defined in the concrete base class, the schema cannot include a `discriminator` field.

Add metadata with a schema transformer

A schema transformer can be used to override any default metadata or add additional metadata, such as `example` values, to the generated schema. See Use schema transformers for more information.

Customize OpenAPI documents

Article • 11/04/2024

OpenAPI document transformers

This section demonstrates how to customize OpenAPI documents with transformers.

Customize OpenAPI documents with transformers

Transformers provide an API for modifying the OpenAPI document with user-defined customizations. Transformers are useful for scenarios like:

- Adding parameters to all operations in a document.
- Modifying descriptions for parameters or operations.
- Adding top-level information to the OpenAPI document.

Transformers fall into three categories:

- Document transformers have access to the entire OpenAPI document. These can be used to make global modifications to the document.
- Operation transformers apply to each individual operation. Each individual operation is a combination of path and HTTP method. These can be used to modify parameters or responses on endpoints.
- Schema transformers apply to each schema in the document. These can be used to modify the schema of request or response bodies, or any nested schemas.

Transformers can be registered onto the document by calling the AddDocumentTransformer method on the OpenApiOptions object. The following snippet shows different ways to register transformers onto the document:

- Register a document transformer using a delegate.
- Register a document transformer using an instance of IOpenApiDocumentTransformer.
- Register a document transformer using a DI-activated IOpenApiDocumentTransformer.
- Register an operation transformer using a delegate.
- Register an operation transformer using an instance of IOpenApiOperationTransformer.
- Register an operation transformer using a DI-activated IOpenApiOperationTransformer.
- Register a schema transformer using a delegate.

- Register a schema transformer using an instance of IOpenApiSchemaTransformer.
- Register a schema transformer using a DI-activated IOpenApiSchemaTransformer.

C#

```
using Microsoft.AspNetCore.OpenApi;
using Microsoft.OpenApi.Models;

var builder = WebApplication.CreateBuilder();

builder.Services.AddOpenApi(options =>
{
    options.AddDocumentTransformer((document, context, cancellationToken)
                            => Task.CompletedTask);
    options.AddDocumentTransformer(new MyDocumentTransformer());
    options.AddDocumentTransformer<MyDocumentTransformer>();
    options.AddOperationTransformer((operation, context, cancellationToken)
                           => Task.CompletedTask);
    options.AddOperationTransformer(new MyOperationTransformer());
    options.AddOperationTransformer<MyOperationTransformer>();
    options.AddSchemaTransformer((schema, context, cancellationToken)
                           => Task.CompletedTask);
    options.AddSchemaTransformer(new MySchemaTransformer());
    options.AddSchemaTransformer<MySchemaTransformer>();
});

var app = builder.Build();

app.MapOpenApi();

app.MapGet("/", () => "Hello world!");

app.Run();
```

Execution order for transformers

Transformers execute in first-in first-out order based on registration. In the following snippet, the document transformer has access to the modifications made by the operation transformer:

C#

```
var builder = WebApplication.CreateBuilder();
```

```
builder.Services.AddOpenApi(options =>
{
    options.AddOperationTransformer((operation, context, cancellationToken)
                                     => Task.CompletedTask);
    options.AddDocumentTransformer((document, context, cancellationToken)
                                     => Task.CompletedTask);
});

var app = builder.Build();

app.MapOpenApi();

app.MapGet("/", () => "Hello world!");

app.Run();
```

Use document transformers

Document transformers have access to a context object that includes:

- The name of the document being modified.
- The ApiDescriptionGroups associated with that document.
- The IServiceProvider used in document generation.

Document transformers can also mutate the OpenAPI document that is generated. The following example demonstrates a document transformer that adds some information about the API to the OpenAPI document.

C#

```
using Microsoft.Extensions.DependencyInjection;
using Microsoft.AspNetCore.Builder;

var builder = WebApplication.CreateBuilder();

builder.Services.AddOpenApi(options =>
{
    options.AddDocumentTransformer((document, context, cancellationToken) =>
    {
        document.Info = new()
        {
            Title = "Checkout API",
            Version = "v1",
            Description = "API for processing checkouts from cart."
        };
        return Task.CompletedTask;
    });
});

var app = builder.Build();
```

```
app.MapOpenApi();

app.MapGet("/", () => "Hello world!");

app.Run();
```

Service-activated document transformers can utilize instances from DI to modify the app. The following sample demonstrates a document transformer that uses the IAuthenticationSchemeProvider service from the authentication layer. It checks if any JWT bearer-related schemes are registered in the app and adds them to the OpenAPI document's top level:

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.OpenApi;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.OpenApi.Models;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAuthentication().AddJwtBearer();

builder.Services.AddOpenApi(options =>
{
    options.AddDocumentTransformer<BearerSecuritySchemeTransformer>();
});

var app = builder.Build();

app.MapOpenApi();

app.MapGet("/", () => "Hello world!");

app.Run();

internal sealed class
BearerSecuritySchemeTransformer(IAuthenticationSchemeProvider
authenticationSchemeProvider) : IOpenApiDocumentTransformer
{
    public async Task TransformAsync(OpenApiDocument document,
OpenApiDocumentTransformerContext context, CancellationToken
cancellationToken)
    {
        var authenticationSchemes = await
authenticationSchemeProvider.GetAllSchemesAsync();
        if (authenticationSchemes.Any(authScheme => authScheme.Name ==
"Bearer"))
        {
            var requirements = new Dictionary<string, OpenApiSecurityScheme>
```

```
            {
                ["Bearer"] = new OpenApiSecurityScheme
                {
                    Type = SecuritySchemeType.Http,
                    Scheme = "bearer", // "bearer" refers to the header name
here
                    In = ParameterLocation.Header,
                    BearerFormat = "Json Web Token"
                }
            };
            document.Components ??= new OpenApiComponents();
            document.Components.SecuritySchemes = requirements;
        }
    }
}
```

Document transformers are unique to the document instance they're associated with. In the following example, a transformer:

- Registers authentication-related requirements to the `internal` document.
- Leaves the `public` document unmodified.

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.OpenApi;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.OpenApi.Models;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAuthentication().AddJwtBearer();

builder.Services.AddOpenApi("internal", options =>
{
    options.AddDocumentTransformer<BearerSecuritySchemeTransformer>();
});
builder.Services.AddOpenApi("public");

var app = builder.Build();

app.MapOpenApi();

app.MapGet("/world", () => "Hello world!")
    .WithGroupName("internal");
app.MapGet("/", () => "Hello universe!")
    .WithGroupName("public");

app.Run();

internal sealed class
```

```
BearerSecuritySchemeTransformer(IAuthenticationSchemeProvider
authenticationSchemeProvider) : IOpenApiDocumentTransformer
{
    public async Task TransformAsync(OpenApiDocument document,
OpenApiDocumentTransformerContext context, CancellationToken
cancellationToken)
    {
        var authenticationSchemes = await
authenticationSchemeProvider.GetAllSchemesAsync();
        if (authenticationSchemes.Any(authScheme => authScheme.Name ==
"Bearer"))
        {
            // Add the security scheme at the document level
            var requirements = new Dictionary<string, OpenApiSecurityScheme>
            {
                ["Bearer"] = new OpenApiSecurityScheme
                {
                    Type = SecuritySchemeType.Http,
                    Scheme = "bearer", // "bearer" refers to the header name
here
                    In = ParameterLocation.Header,
                    BearerFormat = "Json Web Token"
                }
            };
            document.Components ??= new OpenApiComponents();
            document.Components.SecuritySchemes = requirements;

            // Apply it as a requirement for all operations
            foreach (var operation in document.Paths.Values.SelectMany(path
=> path.Operations))
            {
                operation.Value.Security.Add(new OpenApiSecurityRequirement
                {
                    [new OpenApiSecurityScheme { Reference = new
OpenApiReference { Id = "Bearer", Type = ReferenceType.SecurityScheme } }] =
Array.Empty<string>()
                });
            }
        }
    }
}
```

Use operation transformers

Operations are unique combinations of HTTP paths and methods in an OpenAPI document. Operation transformers are helpful when a modification:

- Should be made to each endpoint in an app, or
- Conditionally applied to certain routes.

Operation transformers have access to a context object which contains:

- The name of the document the operation belongs to.
- The ApiDescription associated with the operation.
- The IServiceProvider used in document generation.

For example, the following operation transformer adds `500` as a response status code supported by all operations in the document.

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.OpenApi;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.OpenApi.Models;

var builder = WebApplication.CreateBuilder();

builder.Services.AddAuthentication().AddJwtBearer();

builder.Services.AddOpenApi(options =>
{
    options.AddOperationTransformer((operation, context, cancellationToken)
=>
    {
        operation.Responses.Add("500", new OpenApiResponse { Description =
"Internal server error" });
        return Task.CompletedTask;
    });
});

var app = builder.Build();

app.MapOpenApi();

app.MapGet("/", () => "Hello world!");

app.Run();
```

Use schema transformers

Schemas are the data models that are used in request and response bodies in an OpenAPI document. Schema transformers are useful when a modification:

- Should be made to each schema in the document, or
- Conditionally applied to certain schemas.

Schema transformers have access to a context object which contains:

- The name of the document the schema belongs to.

- The JSON type information associated with the target schema.
- The IServiceProvider used in document generation.

For example, the following schema transformer sets the `format` of decimal types to `decimal` instead of `double`:

C#

```
using Microsoft.AspNetCore.OpenApi;

var builder = WebApplication.CreateBuilder();

builder.Services.AddOpenApi(options => {
    // Schema transformer to set the format of decimal to 'decimal'
    options.AddSchemaTransformer((schema, context, cancellationToken) =>
    {
        if (context.JsonTypeInfo.Type == typeof(decimal))
        {
            schema.Format = "decimal";
        }
        return Task.CompletedTask;
    });
});

var app = builder.Build();

app.MapOpenApi();

app.MapGet("/", () => new Body { Amount = 1.1m });

app.Run();

public class Body {
    public decimal Amount { get; set; }
}
```

Additional resources

- Use the generated OpenAPI documents

Use openAPI documents

Article • 10/28/2024

Use Swagger UI for local ad-hoc testing

By default, the `Microsoft.AspNetCore.OpenApi` package doesn't ship with built-in support for visualizing or interacting with the OpenAPI document. Popular tools for visualizing or interacting with the OpenAPI document include Swagger UI and ReDoc. Swagger UI and ReDoc can be integrated in an app in several ways. Editors such as Visual Studio and VS Code offer extensions and built-in experiences for testing against an OpenAPI document.

The `Swashbuckle.AspNetCore.SwaggerUi` package provides a bundle of Swagger UI's web assets for use in apps. This package can be used to render a UI for the generated document. To configure this:

- Install the `Swashbuckle.AspNetCore.SwaggerUi` package.
- Enable the swagger-ui middleware with a reference to the OpenAPI route registered earlier.
- To limit information disclosure and security vulnerability, ***only enable Swagger UI in development environments.***

C#

```
using Microsoft.AspNetCore.Authentication;
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.OpenApi;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.OpenApi.Models;

var builder = WebApplication.CreateBuilder();

builder.Services.AddOpenApi();

var app = builder.Build();

app.MapOpenApi();
if (app.Environment.IsDevelopment())
{
    app.UseSwaggerUI(options =>
    {
        options.SwaggerEndpoint("/openapi/v1.json", "v1");
    });

}
```

```
app.MapGet("/", () => "Hello world!");

app.Run();
```

Use Scalar for interactive API documentation

Scalar is an open-source interactive document UI for OpenAPI. Scalar can integrate with the OpenAPI endpoint provided by ASP.NET Core. To configure Scalar, install the `Scalar.AspNetCore` package.

C#

```
using Microsoft.AspNetCore.Builder;
using Microsoft.AspNetCore.OpenApi;
using Microsoft.Extensions.DependencyInjection;
using Microsoft.OpenApi.Models;
using Scalar.AspNetCore;

var builder = WebApplication.CreateBuilder();

builder.Services.AddOpenApi();

var app = builder.Build();

app.MapOpenApi();

if (app.Environment.IsDevelopment())
{
    app.MapScalarApiReference();
}

app.MapGet("/", () => "Hello world!");

app.Run();
```

Lint generated OpenAPI documents with Spectral

Spectral is an open-source OpenAPI document linter. Spectral can be incorporated into an app build to verify the quality of generated OpenAPI documents. Install Spectral according to the package installation directions.

To take advantage of Spectral, install the `Microsoft.Extensions.ApiDescription.Server` package to enable build-time OpenAPI document generation.

Enable document generation at build time by setting the following properties in the app's `.csproj` file":

XML

```xml
<PropertyGroup>
    <OpenApiDocumentsDirectory>$(MSBuildProjectDirectory)
</OpenApiDocumentsDirectory>
    <OpenApiGenerateDocuments>true</OpenApiGenerateDocuments>
</PropertyGroup>
```

Run `dotnet build` to generate the document.

.NET CLI

```
dotnet build
```

Create a `.spectral.yml` file with the following contents.

text

```
extends: ["spectral:oas"]
```

Run `spectral lint` on the generated file.

.NET CLI

```
spectral lint WebMinOpenApi.json
...

The output shows any issues with the OpenAPI document. For example:

```output
1:1  warning  oas3-api-servers       OpenAPI "servers" must be present and
non-empty array.
3:10  warning  info-contact           Info object must have "contact"
object.                         info
3:10  warning  info-description       Info "description" must be present and
non-empty string.       info
9:13  warning  operation-description  Operation "description" must be
present and non-empty string.  paths./.get
9:13  warning  operation-operationId  Operation must have "operationId".
paths./.get

✖ 5 problems (0 errors, 5 warnings, 0 infos, 0 hints)
```
```

.NET OpenAPI tool command reference and installation

Article • 08/06/2024

Microsoft.dotnet-openapi is a .NET Core Global Tool for managing OpenAPI references within a project.

Installation

To install `Microsoft.dotnet-openapi`, run the following command:

.NET CLI

```
dotnet tool install -g Microsoft.dotnet-openapi
```

> **Note**
>
> By default the architecture of the .NET binaries to install represents the currently running OS architecture. To specify a different OS architecture, see dotnet tool install, --arch option. For more information, see GitHub issue dotnet/AspNetCore.Docs #29262.

Add

Adding an OpenAPI reference using any of the commands on this page adds an `<OpenApiReference />` element similar to the following to the `.csproj` file:

XML

```
<OpenApiReference Include="openapi.json" />
```

The preceding reference is required for the app to call the generated client code.

Add File

Options

Expand table

Short option	Long option	Description	Example
-p	--updateProject	The project to operate on.	dotnet openapi add file *--updateProject .\Ref.csproj* .\OpenAPI.json
-c	--code-generator	The code generator to apply to the reference. Options are `NSwagCSharp` and `NSwagTypeScript`. If `--code-generator` is not specified the tooling defaults to `NSwagCSharp`.	dotnet openapi add file .\OpenApi.json --code-generator
-h	--help	Show help information	dotnet openapi add file --help

Arguments

Expand table

Argument	Description	Example
source-file	The source to create a reference from. Must be an OpenAPI file.	dotnet openapi add file *.\OpenAPI.json*

Add URL

Options

Expand table

Short option	Long option	Description	Example
-p	--updateProject	The project to operate on.	dotnet openapi add url *--updateProject .\Ref.csproj* `https://contoso.com/openapi.json`
-o	--output-file	Where to place the local copy of the OpenAPI file.	dotnet openapi add url `https://contoso.com/openapi.json` *--output-file myclient.json*

Short option	Long option	Description	Example
-c	--code-generator	The code generator to apply to the reference. Options are `NSwagCSharp` and `NSwagTypeScript`.	dotnet openapi add url `https://contoso.com/openapi.json` --code-generator
-h	--help	Show help information	dotnet openapi add url --help

Arguments

Argument	Description	Example
source-URL	The source to create a reference from. Must be a URL.	dotnet openapi add url `https://contoso.com/openapi.json`

Remove

Removes the OpenAPI reference matching the given filename from the `.csproj` file. When the OpenAPI reference is removed, clients won't be generated. Local `.json` and `.yaml` files are deleted.

Options

Expand table

Short option	Long option	Description	Example
-p	--updateProject	The project to operate on.	dotnet openapi remove *--updateProject .\Ref.csproj* .\OpenAPI.json
-h	--help	Show help information	dotnet openapi remove --help

Arguments

Expand table

Argument	Description	Example
source-file	The source to remove the reference to.	dotnet openapi remove .*OpenAPI.json*

Refresh

Refreshes the local version of a file that was downloaded using the latest content from the download URL.

Options

Expand table

Short option	Long option	Description	Example
-p	--updateProject	The project to operate on.	dotnet openapi refresh *--updateProject .\Ref.csproj* `https://contoso.com/openapi.json`
-h	--help	Show help information	dotnet openapi refresh --help

Arguments

Expand table

Argument	Description	Example
source-URL	The URL to refresh the reference from.	dotnet openapi refresh `https://contoso.com/openapi.json`

Overview of ASP.NET Core SignalR

Article • 09/18/2024

What is SignalR?

ASP.NET Core SignalR is an open-source library that simplifies adding real-time web functionality to apps. Real-time web functionality enables server-side code to push content to clients instantly.

Good candidates for SignalR:

- Apps that require high frequency updates from the server. Examples are gaming, social networks, voting, auction, maps, and GPS apps.
- Dashboards and monitoring apps. Examples include company dashboards, instant sales updates, or travel alerts.
- Collaborative apps. Whiteboard apps and team meeting software are examples of collaborative apps.
- Apps that require notifications. Social networks, email, chat, games, travel alerts, and many other apps use notifications.

SignalR provides an API for creating server-to-client remote procedure calls (RPC). The RPCs invoke functions on clients from server-side .NET Core code. There are several supported platforms, each with their respective client SDK. Because of this, the programming language being invoked by the RPC call varies.

Here are some features of SignalR for ASP.NET Core:

- Handles connection management automatically.
- Sends messages to all connected clients simultaneously. For example, a chat room.
- Sends messages to specific clients or groups of clients.
- Scales to handle increasing traffic.
- SignalR Hub Protocol

The source is hosted in a SignalR repository on GitHub.

Transports

SignalR supports the following techniques for handling real-time communication (in order of graceful fallback):

- WebSockets

- Server-Sent Events
- Long Polling

SignalR automatically chooses the best transport method that is within the capabilities of the server and client.

Hubs

SignalR uses *hubs* to communicate between clients and servers.

A hub is a high-level pipeline that allows a client and server to call methods on each other. SignalR handles the dispatching across machine boundaries automatically, allowing clients to call methods on the server and vice versa. You can pass strongly-typed parameters to methods, which enables model binding. SignalR provides two built-in hub protocols: a text protocol based on JSON and a binary protocol based on MessagePack. MessagePack generally creates smaller messages compared to JSON. Older browsers must support XHR level 2 to provide MessagePack protocol support.

Hubs call client-side code by sending messages that contain the name and parameters of the client-side method. Objects sent as method parameters are deserialized using the configured protocol. The client tries to match the name to a method in the client-side code. When the client finds a match, it calls the method and passes to it the deserialized parameter data.

Browsers that don't support ECMAScript 6 (ES6)

SignalR targets ES6. For browsers that don't support ES6, transpile the library to ES5. For more information, see Getting Started with ES6 – Transpiling ES6 to ES5 with Traceur and Babel.

ASP.NET Core SignalR supported platforms

Article • 06/18/2024

Server system requirements

SignalR for ASP.NET Core supports any server platform that ASP.NET Core supports.

JavaScript client

The JavaScript client runs on the current Node.js long-term support (LTS) release and the following browsers:

Expand table

Browser	Version
Apple Safari, including iOS	Current†
Google Chrome, including Android	Current†
Microsoft Edge	Current†
Mozilla Firefox	Current†

†*Current* refers to the latest version of the browser.

The JavaScript client doesn't support Internet Explorer and other older browsers. The client might have unexpected behavior and errors on unsupported browsers.

.NET client

The .NET client runs on any platform supported by ASP.NET Core. For example, Xamarin developers can use SignalR for building Android apps using Xamarin.Android 8.4.0.1 and later and iOS apps using Xamarin.iOS 11.14.0.4 and later.

If the server runs IIS, the WebSockets transport requires IIS 8.0 or later on Windows Server 2012 or later. Other transports are supported on all platforms.

Java client

The Java client supports Java 8 and later versions.

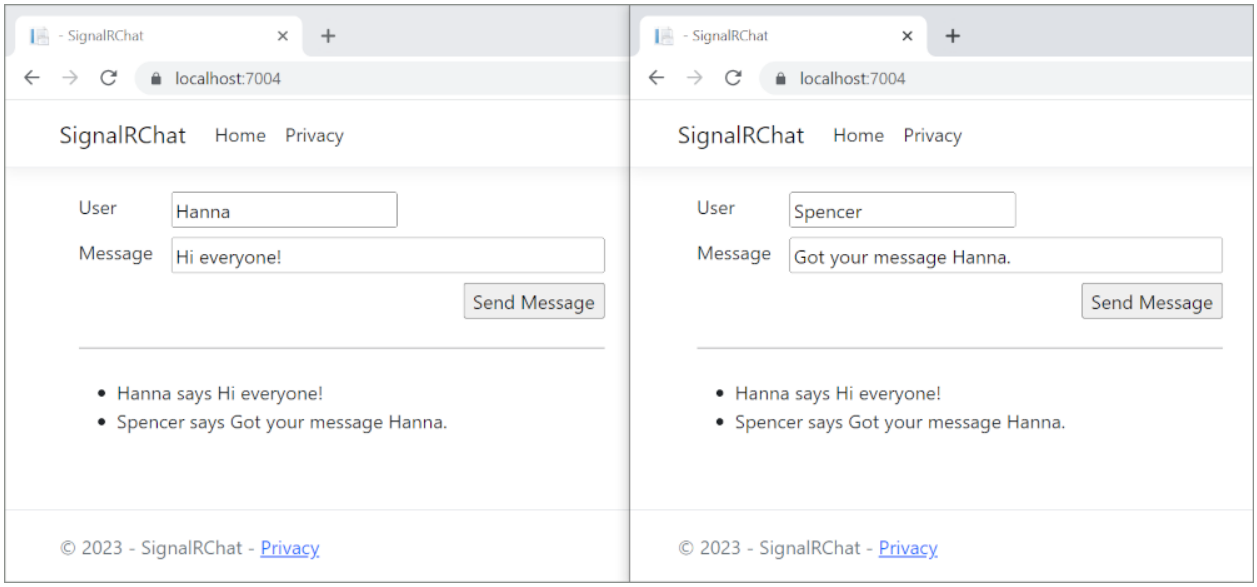
Unsupported clients

The following clients are available but are experimental or unofficial. The following clients aren't currently supported and may never be supported:

- C++ client
- Swift client

Browsers that don't support ECMAScript 6 (ES6)

SignalR targets ES6. For browsers that don't support ES6, transpile the library to ES5. For more information, see Getting Started with ES6 – Transpiling ES6 to ES5 with Traceur and Babel.

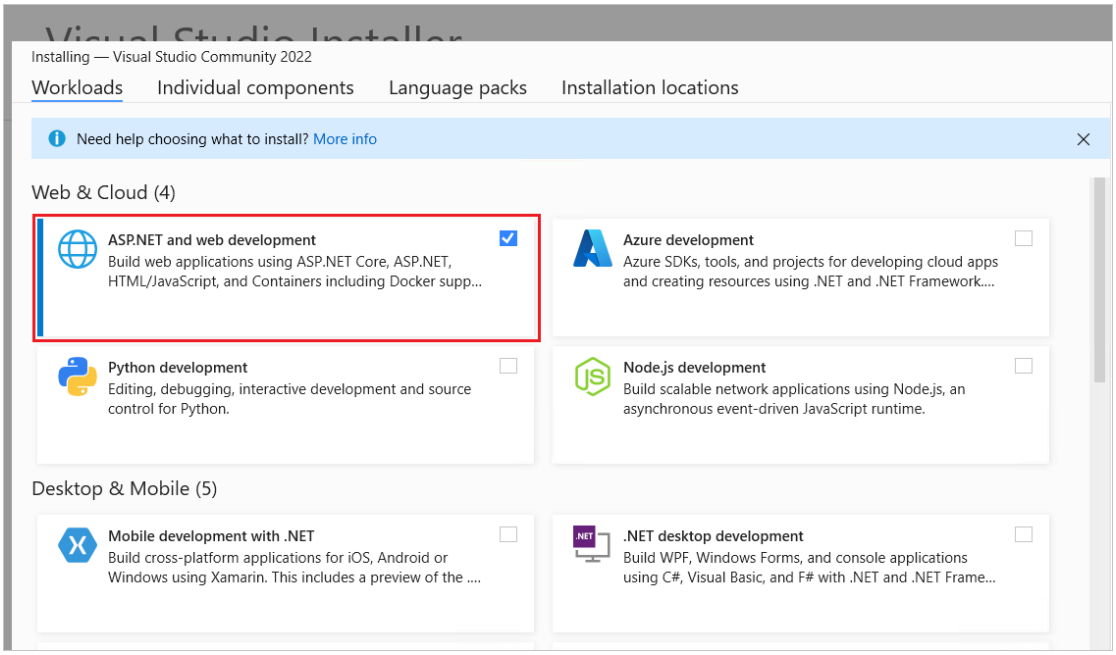


Tutorial: Get started with ASP.NET Core SignalR

Article • 11/16/2023

This tutorial teaches the basics of building a real-time app using SignalR. You learn how to:

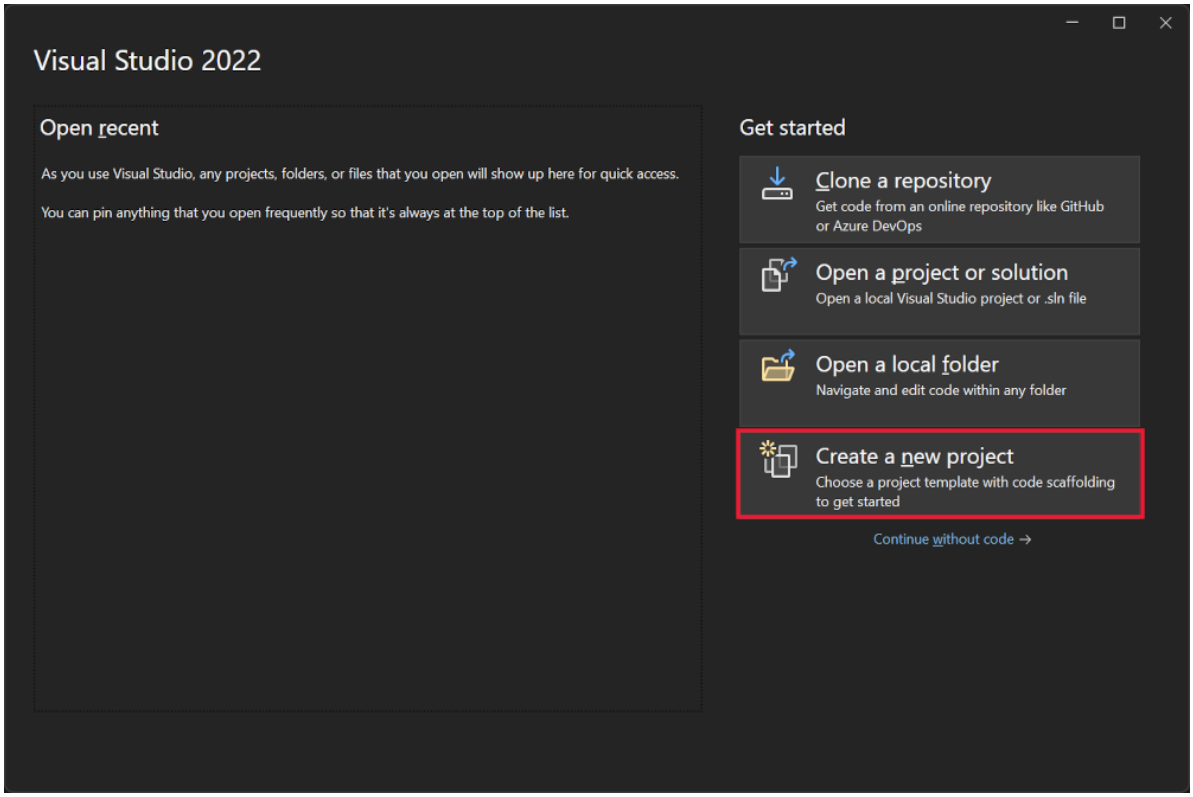
- ✓ Create a web project.
- ✓ Add the SignalR client library.
- ✓ Create a SignalR hub.
- ✓ Configure the project to use SignalR.
- ✓ Add code that sends messages from any client to all connected clients.



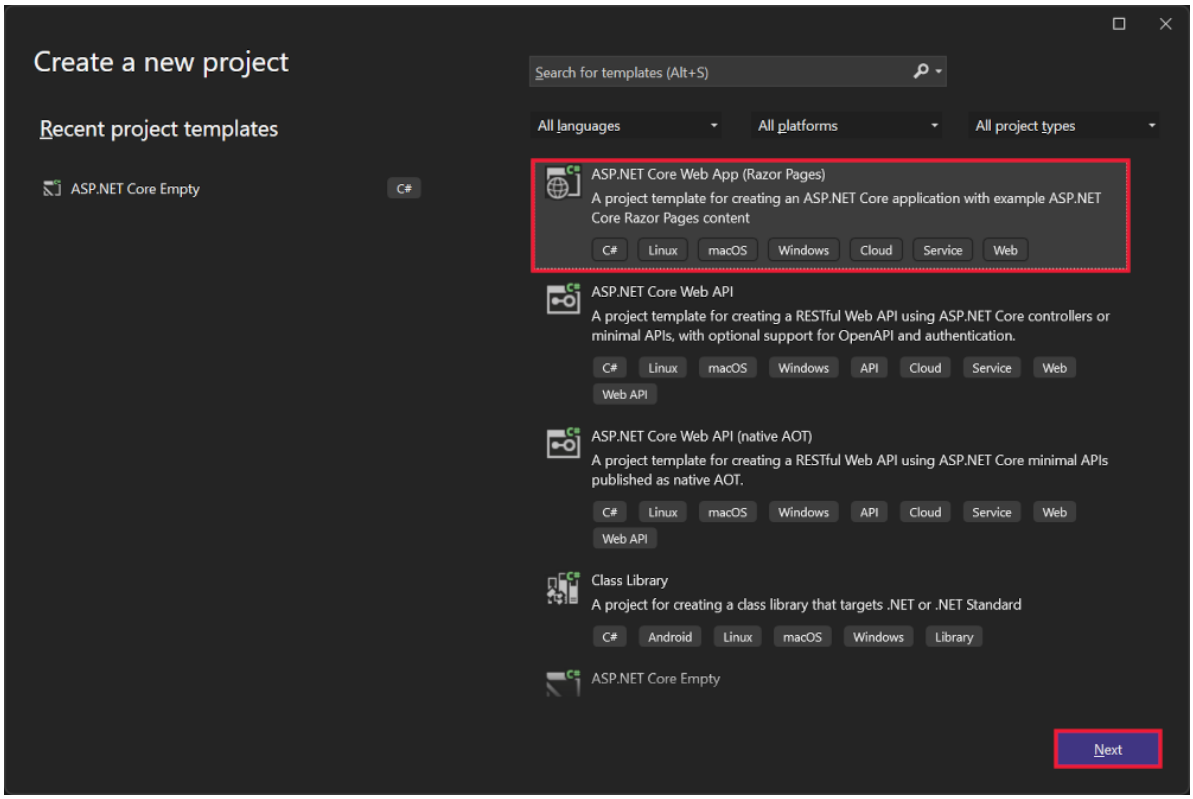
At the end, you'll have a working chat app:

Prerequisites

Visual Studio



- Visual Studio 2022 Preview with the **ASP.NET and web development** workload.



Create a web app project

Visual Studio
